ABSTRACT

Zinc ferrite @ titanium dioxide (ZnFe₂O₄@TiO₂) composite nanofibers were elaborated by combining the two different techniques: electrospinning and plasma enhanced chemical vapour deposition (PECVD). The nanofibers compositions were controlled using different ratio of zinc to iron. Their structural, morphological, and optical properties were analysed by scanning electron microscopy (SEM), X-ray diffraction (XRD), energy-dispersive X-ray spectroscopy (EDX), BET surface area, Raman spectroscopy and UV-Visible

spectrophotometry. The photocatalytic activity has been investigated by the degradation of methylene blue (MB) under visible light. The results indicate that the combination of spinel structure with titanium dioxide improves the photodegradation up to 98%. The deposition of TiO₂ via PECVD on zinc ferrite enhances the absorption of TiO₂ into the visible region and increases the electron-hole separation. In addition, the improved surface area can promote adsorption, desorption and diffusion of reactants and products, which is favourable to obtain a high photocatalytic activity.

INTRODUCTION

The development of the dye industries throughout the planet has led to increase water contamination¹⁻², which implies a serious threat to humans and environment. Therefore, many strategies have been developed in order to remove the organic dyes from wastewater such as chemical flocculation³, adsorption and ion exchange⁴⁻⁶. However, the traditional remediation of dye wastewater has many side effects including the secondary pollution, the low degradation rate and the long processing cycle⁷⁻⁸.

As an alternative approach, photocatalysis has attracted much attention due to its ability to degrade the organic dye in wastewater into environmental friendly compounds such as CO₂ and water⁹⁻¹⁰. Many researchers have focused on semiconductors materials such as TiO₂ and ZnO, due to their high photocatalytic activity¹¹⁻¹². Among these materials, the spinel structure Zinc ferrite (ZnFe₂O₄) has been widely investigated due to its several potential applications, such as gas sensor, electrocatalyst as well as its photocatalytic properties¹³⁻¹⁶. All applications of zinc ferrite are mainly dependent on its surface area and morphology. Thus, many methods have been employed to elaborate different morphologies of zinc ferrite such as core-shell, nanoparticles and nanofibers by hydrothermal, co-precipitation and electrospinning technique, respectively¹⁷⁻¹⁹. In particular, zinc ferrite nanofibers were

synthesised by electrospinning for different applications such as: (i) Preparation of NiZn-ferrite nanofibers by electrospinning for DNA separation ²⁰, (ii) Electrospinning synthesis of ZnFe₂O₄/Fe₃O₄/Ag nanoparticle-loaded mesoporous carbon fibers with magnetic and photocatalytic properties ²¹, (iii) Electrospun ZnFe₂O₄-based nanofiber composites with enhanced super capacitive properties ²² and (iv) Electrospinning synthesis of Ni, Fe co-doped ultrafine-ZnFe₂O₄/C nanofibers for lithium ion storage ²³.

Spinel ZnFe₂O₄ is a low band gap, thus it can be excited by visible light for the degradation of organic pollutants ²⁴⁻²⁵. However, the poor separation efficiency of photo-generated electrons and holes in the ZnFe₂O₄ leads to a low photocatalytic activity ²⁶. The efficiency can be improved by loading different metals such as Ag or Al on the surface of ZnFe₂O₄ ²⁷⁻²⁸. On another hand, titanium dioxide has attracted attention as a photocatalyst (in dye sensitized solar cells, water splitting, self-cleaning and degradation of organic pollutant) due to its relatively low cost, high stability and low toxicity.²⁹⁻³⁰ However, the high recombination rate between the electron-hole of TiO₂ limits the efficiency of the photocatalytic reaction. In addition, TiO₂ has a wide band gap (3.2 eV) and it can only be excited by UV light. Therefore, the use of solar light which contain 44% of visible light and 7% of UV light appears to be quite difficult ^{9, 31}. In order to shift the absorption edge of TiO₂ to the visible range, several processes have been carried out, such as (i) Conjugation with semiconductor that has small band gap ³²⁻³⁴, (ii) Addition of transition metals ³⁵⁻³⁶, (iii) Doping with non-metal elements ³⁷⁻³⁸, (iv) Co-catalyst loading ³⁹⁻⁴³ and (v) Mesoporous silicon nanopillars (NPL) ⁴⁴.

In this paper, electrospinning and Plasma-Enhanced Chemical Vapour Deposition (PECVD) techniques have been combined to produce special forms of ZnFe₂O₄@TiO₂ nanofibers. Among all techniques used to prepare zinc ferrite, electrospinning is a simple and cost-effective technique. It permits the synthesis of nanofibers with controllable diameters ranging

from a few to several hundred nanometers.⁴⁵⁻⁴⁶ Mesoporous structure could be also obtained depending on processing conditions. In addition, plasma processes are very competitive to insure stability, integrity and compactness of the material. Among plasma processes, Plasma-Enhanced Chemical Vapour Deposition (PECVD) is a very promising low-temperature one-step method for deposition and stacking of TiO₂ onto nanofibers substrates. This versatile method enables optimization of structural and functional properties of composite to get promising materials. In the present work, the plasma enhanced chemical vapour deposition (PECVD) method has been applied for the first time to elaborate ZnFe₂O₄@TiO₂ mesoporous nanofibers with high surface area. The structural, morphological and optical properties of the prepared samples have been analyzed. The performance of these materials for photocatalytic degradation of methylene blue under visible light has also been evaluated.

EXPERIMENTAL SECTION

1. Chemicals and materials

Zinc nitrate hexahydrate (99.99%, 228737), Iron(III) nitrate nonahydrate (99.99%, 216828), titanium tetra-isopropoxide (TTIP) Ti(OCH(CH₃)₂)₄ (97%, 205273), polyvinylpyrrolidone (PVP) (M_w = 1 300 000 g/mol) (437190), acetic acid (98%, 33209), (DMF) N,N-dimethylformamide (99.8%, 33120) and methylene blue (MB) (M9140) were purchased from Sigma Aldrich, and used without any further purification. Absolute ethanol (99%, 20821.310) was purchased from VWR PROLABO Chemicals.

2. Preparation of zinc ferrite nanofibers

The zinc combined with iron nanofibers was prepared by the electrospinning technique.⁴⁷⁻⁴⁸ The polymer solution was prepared as follows: 1 g of PVP was dissolved in 9 mL of absolute ethanol. Then, different molar ratios of Zn:Fe (1:0, 1:1, 1:2 and 1:3) were used to fabricate

nanofibers with different amounts of Zn and Fe. The naming of the samples ZF0, ZF1, ZF2 and ZF3 refers to [Z – zinc and F – iron] . Numbers 0, 1, 2 and 3 were referred to different molar ratios of Zn:Fe (1:0, 1:1, 1:2 and 1:3) respectively. Zinc nitrate and iron nitrate were completely dissolved in 5 mL of N,N-dimethylformamide (DMF) with vigorous stirring to form a homogeneous solution. 0.8 mL of metal-DMF was added dropwise to the PVP solution with low stirring for 2 hours. Finally, 1 mL of acetic acid was added to the mixture with low stirring for 1 hour. The homogeneous solution was typically extruded through a stainless steel nozzle with a diameter of 0.7 mm at a constant flow rate of 0.5 ml/h. The feeding flow rate was controlled by a syringe pump. The temperature inside the electrospinning chamber was fixed around $38 \pm 5^\circ \text{C}$. The nanofibers were collected on a rotating coil covered with an aluminium foil with a rotation speed of 400 rpm. A high voltage of 1.8 KV/cm was applied. In the electrospinning process, a high applied voltage was achieved by connecting the positive and ground terminals to the nozzle and the metallic collector, respectively. During the electrospinning, the applied electric field overcomes the surface tension of the polymeric solution, that way ejecting a continuous jet which upon subsequent solvent evaporation and bending produces nanofibers on the collector surface.

3. Deposition of TiO₂ by PECVD (Plasma Enhanced Chemical Vapour Deposition)

Before deposition, the base pressure in the chamber was maintained at 1 Pa by pumping. The liquid precursor titanium tetra-isopropoxide (TTIP) was maintained in an oil bath at 80 °C. The inert argon was bubbling in the TTIP liquid as a carrier gas; the carrying line was heated at 100 °C in order to avoid any condensation of the precursor. Oxygen was introduced as an oxidant gas. R.F. power generator (CESARTM 136) coupled with a matching box (RF Navio, Advanced Energy) was connected to an inner electrode (diameter 10 cm) on top of the chamber. The bottom electrode (diameter 10 cm) and the chamber body were grounded. The

substrate (i.e. bottom electrode) was heated with a heating device (Eurotherm) up to 150° C. The optimum sample ZF2 was used as substrate in a 7 cm a hollow stainless steel dish. The oxygen partial pressure controlling the oxygen flux was set to 0.17 mbar. The partial pressure of TTIP mixed with Ar was 0.225 bars. The distance between the two electrodes (d_p) was 3.0 cm and the discharge power equal to 50 W. The deposition time was 1 h to produce ZF2T. Schematic diagram of plasma reactor is presented in Figure S1. All prepared composite nanofibers were collected and then calcined in a furnace at 550° C with a heating rate of 1° C/min for 3 h in air.

4. Characterisations of materials

The crystalline phase of the materials was analysed by X-ray diffraction (XRD), using a PANalytical Xpert-PRO diffractometer equipped with an Xcelerator detector using Ni-filtered Cu-radiation ($\lambda = 1.54 \text{ \AA}$). The scan step size was fixed to 0.0167 °/step and the time per step was 0.55 sec/step. Raman spectra were obtained from Horiba XploRA, $\lambda = 659 \text{ nm}$ at a power of 20 W with the following acquisition conditions: continuous mode time of 10 seconds, snapshot time of 7 seconds, number of accumulations set to 30 time and a microscope objective lens of 100x. Scanning electron microscopy (SEM) images were taken with a Hitachi S4800, Japan. Energy-dispersive X-ray spectroscopy analysis (EDX) and elemental mapping were performed with a Zeiss EVO HD15 microscope coupled with an Oxford X-MaxN EDX detector. The UV-VIS absorbance spectra were recorded by a Jasco V-570 UV-VIS-NIR spectrophotometer. The surface area of the samples was determined from nitrogen adsorption–desorption isotherms at liquid nitrogen temperature using Micromeritics ASAP 2010 equipment (outgassing conditions: 200°C – 12 h).

5. Photocatalytic reaction

20 mg of each photocatalyst was added into 20 mL of MB aqueous solution ($C = 20 \text{ mg/L}$). MB was used as a reference for organic pollutants. The mixture was magnetically stirred in the dark for 30 min before light irradiation in order to establish the adsorption–desorption equilibrium. Then, the mixture was irradiated by a 500 W linear halogen lamp (the wavelength distribution was in visible region) under continuous stirring. The emission spectrum of the halogen lamp is in the range 420 to 600 nm.⁴⁹ The reaction temperature was kept constant at 25° C by circulating water in a cylindrical tube surrounding the photo-reactor during the entire experiment. The distance between the lamp and the dye solution was maintained at 10 cm. Every 30 min, 2 mL of the sample solution was taken out and centrifuged to remove the catalyst. The centrifuged solutions were analysed by a UV-VIS spectrometer. The photocatalytic degradation efficiency was calculated as follows:

$$\text{Degradation efficiency (\%)} = (C_0 - C)/C_0 * 100 \quad \text{equation (1)}$$

Where C_0 , is the initial concentration of the dye before degradation and C , is the final concentration of the dye after degradation⁵⁰.

RESULTS AND DISCUSSION

The XRD patterns of all prepared materials ZF0, ZF1, ZF2, ZF3 and ZF2T are presented in Figure 1. It can be seen that ZF0 has peaks characteristic of the ZnO phase (JCPDS No. 01-089-1397) with major lattice planes structure (100), (002) and (101) corresponding to $2\theta = 31.77, 34.34$ and 36.23° respectively. The disappearing of (002) and (101) planes in ZF1 is due to the overlapping with the (311) plane at $2\theta = 35.33^\circ$ of the franklinite ZnFe_2O_4 . In ZF2, the pure phase of ZnFe_2O_4 was detected (JCPDS No. 00-022-1012)⁵¹⁻⁵³. For ZF3, the peak at $2\theta = 33^\circ$ corresponds to Fe_2O_3 and is related to the major plane (222) of iron oxide (JCPDS No. 00-039-0238). When TiO_2 was deposited on ZF2 (ZF2T sample), the main peak of anatase was detected at $2\theta = 25.2^\circ$ related to the (101) plane (JCPDS No. 00-021-1272). In

the case of ZF2T, the broad peak at 53° is obtained from the overlapping of franklinite peaks at 53.1° and 56.6° with anatase peaks at 53.9° and 55.1°. The franklinite peaks are shifted to low angle in ZF2T sample compared with tZF2 sample (Figure 1b). This shift is certainly due to the formation of TiO₂ on the surface of ZnFe₂O₄. Moreover it can be supposed that the incorporation of Ti⁴⁺ ions in the ZnFe₂O₄ lattice did not happen in this case because the incorporation of Ti⁴⁺ should induce a shift to higher angle since the radius of Zn²⁺ (0.074 nm) and Fe³⁺ (0.0645 nm) is larger than that of Ti⁴⁺ (0.0605 nm) ⁵¹.

The crystallite average sizes of zinc ferrite with different amounts of iron were estimated using the Scherrer equation ⁹. The calculated results (Table 1) show that the crystallite sizes are decreasing with the increasing of iron ratio. We can suggest that the iron is a grain-growth inhibitor for the franklinite ZnFe₂O₄ from ZF1 to ZF3.

Figure 1. XRD patterns of all prepared nanofibers ZF0, ZF1, ZF2, ZF3 and ZF2T on the 2θ range $20-80^\circ$ (A) and on the 2θ range $34-37^\circ$ (B).

Table 1. Grain size of zinc ferrite with different iron ratios

	ZF1	ZF2	ZF3	ZF2T
Grain size (nm)	20.6	19.6	19.1	17.0

The obtained materials were characterized as well by Raman spectroscopy (Figure 2). In ZF0, the observed peak at 437.32 cm^{-1} was attributed to the E_{2h} mode which is the strongest mode in the ZnO wurtzite crystal structure. The peak at 586.7 cm^{-1} corresponds to E_{1L} mode of ZnO⁵². In addition to these first-order modes, the Raman spectra also show another peak at 327.29 cm^{-1} , which is attributed to a combination of the first-order modes and an overtone, identified

as M point phonons $2-E_2(M)$ of ZnO. From Figure 2, it is clear that the formation of $ZnFe_2O_4$ leads to the decrease of the E_{2h} intensity. In addition, the broad peak at 615.33 cm^{-1} in ZF1 sample can be attributed to the spinel structure of ferrite $ZnFe_2O_4$. This peak refers to the A_{1g} mode of the symmetric stretch of tetrahedral FeO_4 ⁵¹. In ZF2, E_{2h} mode disappears indicating the formation of pure phase of zinc ferrite. The E_g that appears at 333.5 cm^{-1} is due to the symmetric bending of oxygen ions with respect to Fe⁵³. After deposition of TiO_2 on ZF2 (ZF2T sample), all the vibrations modes of anatase appear at 144.8 cm^{-1} (E_g), 198 cm^{-1} (E_g), 395.2 cm^{-1} (B_{1g}), 514 cm^{-1} (A_{1g}) and 634 cm^{-1} (E_g)⁵⁴. Beside the E_g band of zinc ferrite at 329.1 cm^{-1} is observed. The broad peak at 634 cm^{-1} (E_g) has been blue shifted in comparison with the previous studies of Vahtrus *et al.* (2015)⁵⁴. This shifting is attributed to the overlapping with zinc ferrite peak at 615.33 cm^{-1} .

Figure 2. Raman shift of ZF0, ZF1, ZF2, ZF3 and ZF2T samples.

Scanning electron microscopy was used to investigate the morphological features of the prepared nanofibers. It was found that the morphology of the prepared nanofibers strongly depends on the Zn/Fe ratio, as presented in Figure 3. ZF0 sample presents a rod like morphology whereas ZF1 sample presents a nanofiber morphology. With a further increase of iron concentration (ZF2 and ZF3 samples), ZnFe₂O₄ with an optimum nanofibers structure was obtained (Figure 3). The obtained nanofibers in ZF2T after TiO₂ deposition are shorter than ZF2 due to the plasma impact on the fibers. However, the fibers morphology is still preserves.

Furthermore, Ti, Fe, Zn and O elements were detected in EDX mappings for ZF2T, as presented in Figure S2. The distribution of TiO₂ is uniform on the surface of ferrite nanofibers. The composition presented in **Table 2** confirms the formation of ZnFe₂O₄@TiO₂ nanofibers.

Figure 3. Scanning electron microscope images of ZF0, ZF1, ZF2, ZF3 and ZF2T samples.

Table 2. EDX data showing the composition of ZF2T.

Element	Atomic % (error: 1%)
O	67.5
Ti	8.5
Fe	16.3
Zn	7.7

The surface properties and pore structure parameters of the prepared samples were studied using nitrogen adsorption/desorption isotherm. The Barrett–Joyner–Halenda (BJH) pore size distribution is illustrated in Figure S2. From BET (Barrett–Emmett–Teller) method, we found a surface area of 31.18, 59.38, 77.86, 61.83 and 158.51 m²/g for ZF0, ZF1, ZF2, ZF3 and ZF2T, respectively. As shown in Figure S3, the isotherms of ZF2 and ZF2T are of type IV and display a distinct hysteresis loop, which indicates the mesoporous structure of the samples⁵⁵. It is clear that the ZF2T has a high specific surface area (158.51 m²/g) and it maintains the multi-porosity of ZF2 nanofiber with enriched average pore volume (from 0.009 to 0.046 cm³/g). This could result from the elimination of PVP in ZF2 nanofibers during the TiO₂ plasma deposition. Such mesoporous structure with a very high surface area has not been recorded before for this material. This composite material can certainly promote adsorption, desorption and diffusion of reactants and products, which is favourable to obtain a high photocatalytic activity⁵⁶. This composite ZF2T has a wide pore size distribution in the range of 2 to 11 nm, which might be beneficial for the adsorption of contaminant molecules in the liquid system. Moreover, the well-defined transport path of multi-porous ZF2T nanofibers is helpful for charge carrier.

The photocatalytic activity is controlled by the four mechanisms: the photoabsorption, the generation of electron-hole pairs, the charge carrier transfer and the charge carrier's utilization. ZF2T has the best absorption properties as confirmed in BET data. In another hand, the enhancement of the photocatalytic activity is mainly caused by the efficient generation and the transfer of the electron-hole pairs, which depend on the band gap structure of the photocatalyst.

The band gap of samples (E_g) was determined by the following equation:

$$\alpha h\nu = A(h\nu - E_g)^{n/2} \quad \text{equation (2)}$$

where α is the absorption coefficient, ν is light frequency and n is a proportionality constant. The value of n is determined by the transition of semiconductor, i.e. direct transition as for zinc ferrite ($n = 1$) or indirect transition as for TiO_2 ($n = 4$). The diffuse reflectance of all prepared samples is presented in Figure 4. In addition, the absorption edge of ZF2T had relatively steep edges, indicating that the absorption in the visible region was not due to the surface states but rather to an intrinsic band transition⁵⁷. The E_g values of all samples are listed in Table 3. Where E_{g1} of ZF0 was presented for ZnO, E_{g1} of ZF2T (IT) – indirect transitions for TiO_2 , E_{g2} values were displayed for ZnFe_2O_4 and E_{g3-5} were referred to Fe_2O_3 . These results indicate that ZF2T composites could absorb more photons which enhance the photocatalytic process.

Furthermore, the conduction band (ΔE_C), the valence band offsets (ΔE_V), the fermi level (E_F) and the built in potential (V_{bi}) are calculated in Table 4 by the following equations:⁵⁸

$$\Delta E_C = \mathcal{X}_2 - \mathcal{X}_1 \quad \text{equation (3)}$$

$$\Delta E_V = E_{g1}(\text{IT}) - E_{g1}(\text{DT}) - \Delta E_C \quad \text{equation (4)}$$

$$E_F = \phi - \mathcal{X} \quad \text{equation (5)}$$

$$V_{bi} \cdot q = E_{F2} - E_{F1} \quad \text{equation (6)}$$

Where, $\chi_{1,2} = 4.35$ and 4.19 eV are electron affinity values of zinc ferrite and TiO_2 , respectively.⁵⁹ $E_{g1}(\text{IT})$ and $E_{g1}(\text{DT})$ are the band gap values from Table 3. ϕ is the work function presented in Table 4.⁶⁰ q is electron charge and $E_{F1,2}$ are Fermi level positions of TiO_2 and zinc ferrite, respectively.

	Electron affinity (eV)	Band gap (eV)	Work function (eV)	ΔE_C (eV)	ΔE_V (eV)	V_{bi} (eV)
Zinc ferrite	4.35 ⁵⁹	2.78	4.56 ⁵⁹	0.16	0.33	0.02
TiO ₂	4.19 ⁵⁹	3.27	4.38 ⁵⁹			

The photoluminescence spectra of all prepared samples are shown in Figure 5. A drastic quenching of PL intensity of ZF2T was observed after the introduction of TiO₂ with zinc ferrite, indicating that the recombination of the photo-generated charge carriers was greatly reduced in the obtained materials.⁶⁰ This phenomenon could be attributed to the phase transitions. As it can be seen, the wavelength of the peak was shifted in ZF1 sample due to the disappearing of ZnO. This result matches well with the XRD data presented above.

Figure 5. Photoluminescence of ZF0, ZF1, ZF2, ZF3 and ZF2T nanofibers.

The photocatalytic activities of zinc ferrite with different ratios of iron with or without deposition of titanium dioxide by PECVD were evaluated for the degradation of methylene blue under visible light. The MB is difficult to be photodegraded in the absence of a photocatalyst as shown in Figure 6. After 30 minutes in dark, the adsorption-desorption equilibrium was established as presented in Figure S4. The degradation of MB is up to 15%, 40%, 50%, 38% and 98% for ZF0, ZF1, ZF2, ZF3 and ZF2T respectively (Figure 6). It is well known that the enhancement of the photocatalytic activity depends on the specific surface area, crystallinity, light absorption capacity and separation efficiency of electron-hole pairs.⁶¹⁻⁶² Therefore, the good photocatalytic activity of the ZF2T sample is directly related to its high surface area and quenching of photoluminescence due to the effect of spinel structure with TiO₂. Moreover, a very high surface area has previously been recorded for this material

(ZnFe₂O₄@TiO₂ nanofibers) in comparison with the previously studied ZnFe₂O₄/TiO₂ nanoparticles (surface area : 36 m²/g).⁶³ The enhancement of surface area is another reason for the improvement of the photocatalytic activity.

The photodegradation rate was clarified by the degradation kinetic linear curves which are presented in Figure 7. The photodegradation reactions follow a Langmuir Hinshelwood first order kinetics model. The equation is described as follow:

$$r = dC/dT = kKC/(1+KC) \quad \text{equation (7)}$$

Where r is the rate of MB degradation (mg L⁻¹ min⁻¹), C is the concentration of the MB solution (mg L⁻¹), t is the degradation time, k is the reaction rate constant (mg L⁻¹ min⁻¹), and K is the adsorption coefficient of MB (mg L⁻¹). The relationship between $\ln(C_0/C)$ and the reaction time (t) shows that the decomposition of MB with different photocatalysts follows a pseudo first order kinetic:

$$\ln(C_0/C) = kKT = k_a t \quad \text{equation (8)}$$

where k_a is the apparent first-order rate constant (min⁻¹) and C is the concentration at time t . k_a reported in Table 5 is obtained from the linear dependence between $\ln(C_0/C)$ and time. The rate constants are increasing in the following order: ZF2T > ZF2 > ZF1=ZF3 > ZF0. The rate constant exhibits a maximum of 0.022 min⁻¹ for ZF2T. From the obtained results, it is evident that the produced ZnFe₂O₄@TiO₂ nanofibers by electrospinning and PECVD show a very high surface area with mesoporous structure and good properties for the separation of photo-induced electron-hole pairs of TiO₂. These characteristics significantly increase their photocatalytic activity under visible light, as proved by their very high performance in the degradation of methylene blue under visible light by comparison with previous studies (Table 6).^{62, 64-66}

The degradation mechanism, based on all above-mentioned results, the energy band structure of ZnFe₂O₄@TiO₂ hetero-interfaces is schematically shown in Figure 8. Zinc ferrite is a p-

type semiconductor, while TiO₂ is an n-type semiconductor. Separately, the band gap of n-type TiO₂ is larger than those of p-type Zinc ferrite, and the Fermi level of ZnFe₂O₄ is lower than that of TiO₂. When they are in contact, the Fermi level of TiO₂ is moved down and the Fermi level of ZnFe₂O₄ is moved up until an equilibrium state is formed. Under light irradiation, electrons and holes are generated in the junction. The charges are driven by the internal electric field (the built-in potential V_{bi}). The photogenerated electrons in the conduction band of the p-type ZnFe₂O₄ cannot transfer to that of n-type TiO₂ because of the barrier established at the junction. Only a small amount can be transferred by the tunnel effect through the electric potential barrier near the junction. The photo-generated holes in TiO₂ can instead migrate from the valence band of n-type TiO₂ to that of p-type ZnFe₂O₄ because of the gradient established at the junction, so leaving an excess of negative charge in the TiO₂. These results are important in cationic dyes as MB.⁶⁷ The photogenerated holes have a strong oxidizing power to produce OH[•] radicals. In the same time the photogenerated electrons are enough to produce O₂^{•-} from molecular oxygen; following this mechanism:

CONCLUSION

In this study, by combining the two techniques electrospinning and PECVD, a novel ZnFe₂O₄@TiO₂ nanofibers structure with high surface area was successfully manufactured. The photocatalytic activity was evaluated through MB dye degradation under visible light. The prepared zinc ferrite nanofibers with TiO₂ displays the best activity (98% degradation ratio of pollutant) compared to the same sample without TiO₂ (50% degradation ratio of pollutant). Zinc ferrite@TiO₂ acts as p-n junction to keep the electrons on the surface of TiO₂

inducing enhanced photodegradation of pollutant. Some electrons can accumulate on the surface of ZnFe₂O₄@TiO₂ as confirmed by quenching of photoluminescence. As a conclusion, the zinc ferrite coated with TiO₂ has a very high potential to enhance the photocatalytic efficiency in the degradation of organic pollutant under visible light.

ASSOCIATED CONTENT

Supporting Information. Additional figures (Schematic diagram of PECVD reactor, Elemental mapping images and distribution of all elements (a) O, (b) Ti, (c) Fe, (d) Zn for ZF2T nanofibers, Isotherms hysteresis loop and pore size distribution of ZF2 and ZF2T and Adsorption equilibrium of MB) were shown in the supporting information.
