HAL is a multi-disciplinary open access archive for the deposit and dissemination of scientific research documents, whether they are published or not. The documents may come from teaching and research institutions in France or abroad, or from public or private research centers.

L’archive ouverte pluridisciplinaire HAL, est destinée au dépôt et à la diffusion de documents scientifiques de niveau recherche, publiés ou non, émanant des établissements d’enseignement et de recherche français ou étrangers, des laboratoires publics ou privés.
Ivabradine: A promising drug in cardiogenic shock to prevent the undesirable sinus tachycardia induced by dobutamine?☆

Keywords:
Heart failure
Dobutamine
Cardiogenic shock
Ivabradine

Severe systolic Heart Failure (HF) and especially the ultimate form represented by cardiogenic shock are associated with a very poor prognosis including a very high in hospital mortality. Inotropic drugs are until now the cornerstone of the management of cardiogenic shock. By contrast, both guidelines from the ACC/AHA and ESC recommend limited use of the inotropic agents for the management of acute HF [1,2]. Indeed, on the one hand these drugs exert a dose dependent inotropic and chronotropic positive effect leading to cardiac output increase and left ventricle (LV) filling pressures decrease, but on the other hand they expose to side-effects such as particularly induced sinus tachycardia that may in turn induce detrimental myocardial ischemia and arrhythmias and importantly as regards pathophysiology sinus tachycardia prevents efficient filling through shortened diastole [3]. Paradoxically, even if tachycardia is known to reduce diastolic duration being then deleterious in this clinical setting, it is also usually considered as a compensatory mechanism deserving to be respected. Although theoretically logical, this common belief should be challenged. Furthermore, although the effect of inotropic drugs is not established with regards to mortality, they are paradoxically given in life-threatening situations. These patients have a poor prognosis and specific clinical trials are extremely difficult to initiate.

Ivabradine has been found to specifically block hyperpolarization-activated cyclic nucleotide-gated (HCN) channels without any effects on other receptors or channels in the cardiovascular system, at therapeutic concentrations (see Fig. 1 for schematic presentation of the mechanisms and see for review [4]). Ivabradine inhibits the If funny current (supported by the HCN channels), an ionic current involved in pacemaking activity in the sinoatrial node. HCN channels are specifically expressed in the heart and the central nervous system and ivabradine reduces heart rate (HR) without depressing myocardial contractility or reducing cardiac output [5,6].

As regards HF, ivabradine is recommended (class IIa, level B) in chronic stable HF in patients in sinus rhythm with a left ventricular ejection fraction (LVEF) ≤ 35%, an HR ≥ 70 bpm, and persisting symptoms (NYHA classes II–IV) despite treatment with an evidence-based dose of β-blocker (or maximum tolerated dose below that), angiotensin-converting enzyme inhibitor (or angiotensin II receptor blockers), and a mineralocorticoid receptor antagonist [2]. Nevertheless, due to lack of data, ivabradine remains until now contra-indicated in case of acute HF and cardiogenic shock, as these situations were considered as exclusion criteria in almost all clinical trials.

Noteworthy, ivabradine has just been reported to potentially exert detrimental effects in another indication (coronary artery disease) and there will be further investigations.

Taking all these considerations together, it could be promising to introduce ivabradine carefully to obtain a selective decrease in HR, with no impact on output and contractility parameters (Fig. 2). This new strategy may improve LV relaxation, decrease oxygen needs and further facilitate inotropic drugs including dobutamine weaning.

Preliminary data supporting this hypothesis are scarce. Experimental data have suggested for decades that ivabradine could exert positive hemodynamic effects in dogs [7]. More importantly the drug has been shown to exert favorable impact on HF including the lowest LV ejection fraction in the main study [8] and some clinical cases are reported [3,9]. More precisely in advanced HF, a small trial in 10 patients has assessed the hemodynamic effects of ivabradine in patients with advanced HF and markedly depressed LV function (LVEF 21+/− 7%). Ivabradine 0.1 mg/kg was infused and hemodynamic effects were carefully monitored. Ivabradine significantly reduced HR, by a maximum of 27% at 4 h, increased stroke volume and LV systolic work by a maximum of 51% (to 66+/− 17 ml) and 53% (to 58+/− 20 g) at 4 h. No serious adverse events occurred [10]. Beyond the acute impact in severe acute HF, favorable LV remodeling could also be hoped as reported in an echocardiographic substudy of the Shift trial [11].

In this issue, Gallet et al. reported promising data in the manuscript entitled “hemodynamic effects of ivabradine in addition to dobutamine in patients with severe systolic dysfunction” [12]. They proposed a double approach: 1 / they assessed first the effects of Ivabradine in addition to dobutamine in stable HF patients (LVEF < 35%, n = 22) in whom they assessed both systolic and diastolic function at rest and under dobutamine [10 ɣ/min], before and after Ivabradine [5 mg per os]; and 2 / they validated the effects of dobutamine in patients with refractory cardiogenic shock (n = 9, validation population) with contraindication to cardiac assistance or transplant. In this latter population, ivabradine [5 mg twice a day] was added to the dobutamine infusion. The authors obtain here promising results. 1 / In the first population, ivabradine decreased HR as expected. More importantly this decrease was associated with a decrease in cardiac power output and an increase in diastolic duration, an improvement in LVEF in both situations. 2 / In the validation population, ivabradine improved diastolic filling time without decreasing cardiac output. At 24 h, ivabradine improved systolic blood pressure, daily urine output, oxygen balance and NT-proBNP. Conclusions on events are obviously difficult to draw, in regard to the very small number of patients. Anyway, they establish in this pilot study the safety and potential benefit of an HR lowering agent in cardiogenic shock. This seems all the more promising as such studies in patients suffering from a severe HF associated with very poor clinical outcomes are extremely difficult to initiate and complete. Secondly,
severe HF with contra-indication for heart transplantation or assistance is not exceptional but remains until now deadlocked. Nevertheless, this study presents limitations as recognized by the authors. They chose to study two distinct populations and provided then accurate and consistent data but the design is a bit unusual. Beyond technical discussions, the open design and above all the very small number of patients prevent to conclude definitely. Some characteristics of the population prevent also from comparing to other ones, such as the very poor adherence to treatments (until half of the patients are contra-indicated to transplantation for this reason).

In conclusion, results presented here are promising and deserve fully to be confirmed or not through large multicenter trials. Although a strict PROBE design could be difficult in such settings, simultaneous exhaustive biological, imaging and hemodynamic assessments should be carefully designed and above all long clinical follow-up remains mandatory. The very question seems to be whether this new approach could offer better survival and not beyond an acute and transient hemodynamics support, which is already the case regarding inotropic agents. Importantly, recent results (the SIGNIFY trial) urge the careful monitoring of adverse events.

Conflict of interest

The authors report the following conflict of interest: FR has received honoraria for lectures and research grants from Servier.
