The Complex QT/RR Relationship in Mice

Julien Roussel¹, Pascal Champeroux², Jérôme Roy¹, Sylvain Richard¹, Jérémy Fauconnier¹, Jean-Yves Le Guennec^{1,*} & Jérôme Thireau^{1,*}

The QT interval reflects the time between the depolarization of ventricles until their repolarization and is usually used as a predictive marker for the occurrence of arrhythmias. This parameter varies with the heart rate, expressed as the RR interval (time between two successive ventricular depolarizations). To calculate the QT independently of the RR, correction formulae are currently used. In mice, the QT-RR relationship as such has never been studied in conscious animals, and correction formulas are mainly empirical. In the present paper we studied how QT varies when the RR changes physiologically (comparison of nocturnal and diurnal periods) or after dosing mice with tachycardic agents (norepinephrine or nitroprusside). Our results show that there is significant variability of QT and RR in a given condition, resulting in the need to average at least 200 consecutive complexes to accurately compare the QT. Even following this method, no obvious shortening of the QT was observed with increased heart rate, regardless of whether or not this change occurs abruptly. In conclusion, the relationship between QT and RR in mice is weak, which renders the use of correction formulae inappropriate and misleading in this species.

In 1906, Wilhem Einthoven published the use of the string galvanometer to record the ECG and described/named the P-Q-R-S-T waves¹, for which he received the Nobel Prize for Physiology or Medicine in 1924. Subsequently, it has been shown that the QT interval, representing the duration of the ventricular depolarization of the action potential (AP), depends on the heart rate (HR). This is known as the QT-RR relationship, the RR interval being the period between two consecutive ventricular depolarizations. This physiological relationship presents great inter- and intra-individual variability, linked to the ortho- and para-sympathetic tones².

An increase in contraction frequency, i.e. the HR, produces a positive inotropic effect whereby the force of the contraction increases and reaches a new steady state within a few beats. This phenomenon is named the “positive staircase”, Treppe or Bowditch effect, and affects the RR and QT intervals. This phenomenon is marked in species with a ventricular action potential characterized by a long plateau phase (as in humans, cats and pigs), which is the cellular expression of the QT^{3,4}. For instance, in humans, an increase in pacing rate can accumulate I_{KS} in the open state and activate the Ca^{2+} dependent Cl^- current (I_{TO2}), resulting in a shortening of the action potential duration (APD)⁵⁻⁸.

Nevertheless, these electrophysiological determinants of the frequency-dependence of the APD differ between species. For example, in lagomorphs or rodents, with a short to very short refractory period, the dependence of the APD on frequency is less clear and could be contrary to the effects seen in humans^{4,9,10}.

QT prolongation secondary to acquired or congenital heart disease or induced by pharmacological compounds is associated with an increased risk of arrhythmias¹¹. Since the QT interval depends on the HR, a correction needs to be applied in order to render the QT interval independent of the RR interval, and to detect any APD changes independent of the HR. Bazett¹² and Fridericia¹³, by analyzing a large number of ECGs, have empirically developed correction formulae that are the most used in humans. These formulas have subsequently been applied in animals, but it has been observed that the corrected QT (QTc) is overestimated at high HRs and underestimated at low HRs¹⁴. For this reason, many groups are attempting to establish an index more predictive of fatal arrhythmias, and more independent of HR correction formulae (see¹⁴ for review). Despite this, the QTc remains the most used index to evaluate the electrical properties of ventricles. Many formulae have been used to better fit specific QT-RR relationships (see¹⁴ for review), and a new formula, which can be adapted to different species or individuals, has recently been proposed^{14,15}. Broadly, this approach, dedicated to pharmacological safety

(D) QT frequency histogram of distribution from the same mouse than in B.

experiments, aims to linearize the QT-RR relationship, in order to characterize individual QT-RR relationships and determine whether compounds modify QT *per se*.

Mice are the most used animal species in research labs and preclinical studies. There are many strains of mice, wild-type or genetically engineered, with well-characterized cardiac electrophysiology^{16,17}. The formulae used to correct the QT in mice are generally formulae developed previously for other species (mostly for humans), but their use sometimes yields quite surprising results, such as a QTc of 160 ms for a mean RR of 130 ms¹⁸. They are therefore empirically weighted to obtain a value of the same order as the raw QT. For example, the original Bazett's formula developed for humans is $QTc = QT/\sqrt{RR}$, while the most used formula in mice is $QTc = QT/\sqrt{RR/100}$, i.e. Bazett's formula normalized to the mean cycle length of this species¹⁹⁻²¹. In addition to correction formulae, the method used to determine the QT over the ECG trace is also of interest. In many studies, QT is measured over small periods, with or without respect to the nycthemeral rhythm, and a correction formula applied subsequently, either by using beat-to-beat RR values, or a mean RR. In other studies, QTc is calculated using complex procedures. For example, Jeyaraj *et al.*²² calculated the QTc with a weighted HR approach where measurements were made every 2 hours over a 24-hour period. The mean hourly HR was calculated, and the QT interval measured only between two consecutive beats separated by an RR corresponding to the mean HR. Subsequently, Mitchell's formula was applied to correct the QT interval hour by hour. Such different approaches make it difficult to compare the results of different studies. A dedicated study to better define the relationship between QT and RR in mice is needed in order to measure and correct the QT in a more accurate, logical and consistent manner.

To do this, we measured the ECG traces of 21 conscious C57Bl6 mice. Between 10000 and 30000 ECG complexes per mouse were analyzed at different periods (diurnal and nocturnal) under basal conditions, and after the injection of either nitroprusside or norepinephrine to evaluate intra-individual variability and the QT-RR relationship in mice.

Our results indicate that in mice, the QT interval depends on the RR interval to a negligible extent, leading us to conclude that correcting the QT, whatever the formula used, has no physiological value at best, and at worst, introduces errors.

Results

Beat-to-beat QT durations and RR intervals were measured during the diurnal and nocturnal periods from ECG signals in 11 male C57Bl/6 mice. Typical examples of the results are shown in Fig. 1. As presented in Fig. 1B, the QT and RR intervals varied considerably during the nocturnal period. An analysis of the distribution of the QT

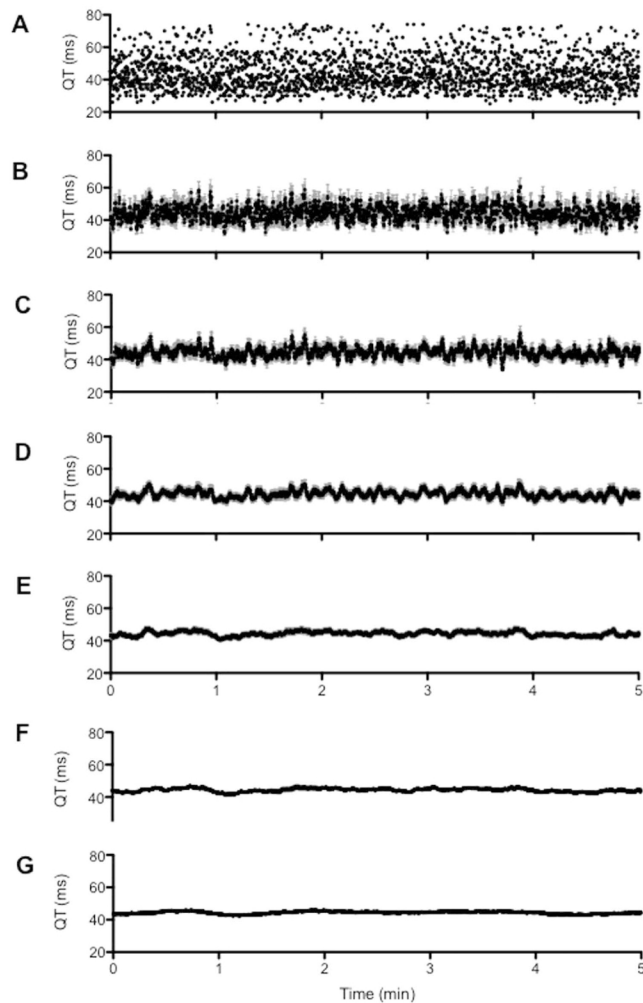

Figure 2. Beat-to-beat variation of the QT interval measured during a 5min time period and filtered thanks to a moving average of different subset sizes. (A) raw QT interval. (B) subset of 5 measurements. (C) subset of 11 measurements. (D) subset of 21 measurements. (E) subset of 51 measurements. (F) subset of 101 measurements. (G) subset of 201 measurements.

and RR intervals over 45–60 minutes during the middle of the nocturnal and diurnal periods indicated that the RR interval followed two Gaussian distributions (Fig. 1C). Although the QT exhibited a wide range of values (between 30 and 60 ms in Fig. 1B), it still followed a single normal distribution curve during both the nocturnal and diurnal periods (Fig. 1D). This suggests that QT is only weakly dependent on the nycthemeral cycle in mice, unlike the HR. One could therefore assume that, depending on the moment when QT intervals are measured, the values obtained could vary significantly independently of the RR. To determine how they vary and whether averaging successive QT values could bypass this problem, we measured all QT values in a 5-minute sequence of diurnal ECG recordings ($n = 2205$ QRS complexes) and compared raw values with those obtained with sliding averages of subsets of 5, 11, 21, 51, 101 and 201 consecutive complexes (Fig. 2). We observed that the extent of QT variation (maximum QT *minus* minimum QT) during the 5 min sequence was 49 ms without averaging, and this decreased to 29, 22.5, 12, 7, 5.6 and 3.4 ms when averaging 11, 21, 51, 101 and 201 consecutive complexes respectively. Thus, in the rest of the present manuscript, QT intervals were calculated by averaging at least 200 complexes.

Figure 1B shows that the data points formed a cloud with no obvious relationship between QT and RR, and where QT varies from ≈ 30 to 60 ms and RR varies from 90 to 160 ms. In addition, the points above and below the cloud are erratic and are not consecutive to abrupt RR changes. Since it was difficult to establish a clear relationship between QT and RR during nocturnal period, we analyzed the ECG during the diurnal period, when the HR is expected to slow down. We thus plotted QT as a function of RR during both the nocturnal and diurnal periods (example in Fig. 3). The relationship between QT and RR was flat ($r^2 = 0.07$) in the example given and could even be negative for some mice (Table 1). Of the 22 QT-RR series analyzed, 4 relationships between QT and RR were not significant, 6 were negative and significant and 12 were positive and significant.

When we compared the mean changes in QT and RR between nocturnal and diurnal periods in 11 mice, we observed that, even if there was a tendency for QT to decrease with decreased RR, this change was not statistically

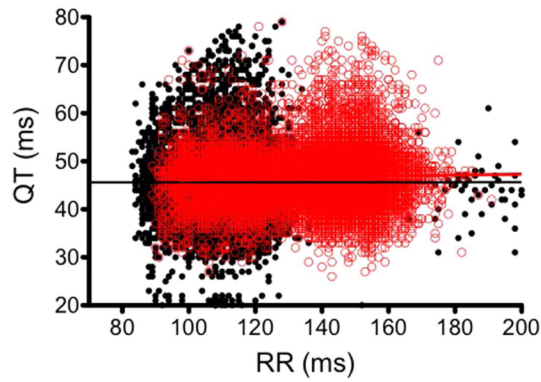

Figure 3. QT-RR relationship recorded over 30min during the nocturnal (black) and the diurnal (red) periods (see Method section). Straight lines indicate the linear regression line calculated during both periods.

Table 1. Parameters of linear regression analysis of the QT-RR relationship of the eleven mice studied in diurnal and nocturnal periods. The linear regression being calculated being: $QT = \text{slope} * RR + \text{Diff}$. r is the Pearson correlation parameter and stats indicates the significance of the correlation. * $p < 0.05$. ns: non significant.

significant and the inter-individual variability was rather large (Fig. 4A). Thus, to decrease this variability, we plotted the variation of QT, expressed as a percentage, during the diurnal as well as during the nocturnal period (Fig. 4B). Here again we could observe that there was a slight, but not significant, tendency for the QT to decrease with decreased RR (also expressed as a percentage of median RR during the diurnal period).

To evaluate the consequences of using correction formulae such as equation (1), which is the most used in the literature¹⁹, we plotted the same data as shown in Fig. 4A,B, but using QTc instead of the raw QT. As shown in Fig. 4C,D, the mean variations in QTc became significant when moving from the diurnal to the nocturnal period. Moreover, and unexpectedly, while RR intervals were longer, QTc values were inversely shorter.

It thus appears that physiological changes in the RR interval due to the nycthemeral cycle are not associated with significant changes in QT. However, this does not rule out the possibility that a QT-RR relationship that is not steep still exists. To test this possibility, we evaluated the impact on the QT interval of rapid and more pronounced changes in the RR interval induced by norepinephrine (NE) or nitroprusside (Fig. 5).

When mice were challenged with NE, there was a rapid and large decrease of the RR interval, but QT intervals did not vary (Fig. 5A). Since NE can directly interfere with the regulation of cardiac electrical activity, we used another tachycardic agent, the vasodilator nitroprusside, which does not have a direct cardiac effect (Fig. 5B).

Figure 4. Influence of the nocturnal and diurnal periods on mean QT-RR relationships of eleven mice. Open circles correspond to the mean values obtained from different animals and the standard deviation in RR and QT are given and the filled circles the individual measurement. (A) Individuals and mean QT-RR relationships during the diurnal (black) and nocturnal periods (red points). (B) Variations in QT and RR expressed in percentage of the respective values obtained during the diurnal period. (C) Individuals and mean QTc-RR relationships during the diurnal and nocturnal periods. The QTc has been calculated according to equation (1). (D) Variations in QTc and RR expressed in percentage of the respective values calculated during the diurnal period.

As observed with NE, changes in the RR were not associated with changes in QT in the minute following the injection. To verify that this poor dependence of the QT on the RR was not due to the low adaptive sensitivity of the QT to the RR, we measured the RR, QT and QTc intervals 15 minutes after drug administration (Fig. 5C,D). In the case of both drugs, correcting the QT with Mitchell's formula introduced an apparent dependence of the QTc on the RR. Again, this dependence was contrary to the expected adaptation of the QT to the stimulation frequency: QTc increased as the HR increased.

Discussion

Hundreds of articles have used the QTc value to assess repolarization time in mice and investigate the effects of environmental changes (due to drugs or disease) on ventricular repolarization. Here, we asked whether there was a QT/RR relationship in mice using two approaches: by investigating the well-known physiological changes in the RR interval during nycthemeral cycles, and by the pharmacological alteration of the HR. Our study principally shows that the QT-RR relationship in mice is so tenuous that, whatever the correction formula chosen, it can only introduce a bias in any calculation that depends solely on changes in the RR interval. Speerschneider & Thomsen have already described the lack of dependence of the QT on the RR in anesthetized mice, and shown that correction formulae erroneously introduce such dependence²³. However, they did not record the ECG in conscious mice, which have a faster HR.

In contrast to other species such as humans, pigs, dogs or guinea-pigs, in which there is a clear QT-RR relationship that needs to be determined for each individual¹⁴, this relationship is not obvious in mice. Thus, precautions need to be taken when interpreting ventricular depolarization time in mice from the raw QT and/or following QT correction. We also uncovered great inter- and intra-individual variability in mice, indicating that a large number of animals is required when analyzing QT parameters, in order for the data to be reliable.

The lack of a QT-RR relationship can be linked to the peculiarity of ventricular repolarization in mice, which starts before the activation of another cardiac territory²⁴⁻²⁶. Moreover, theoretically, the ventricular APD depends on the duration of the preceding diastolic period in a relationship termed "electrical restitution". In humans, the APD becomes shorter with decreasing cycle lengths and thus with decreasing diastolic periods (a phenomenon also named "cardiac memory"). This mechanism allows for an increase in the duration of excitation-contraction coupling during bradycardia (long cycle lengths) while favoring diastolic time for coronary perfusion and ventricular filling when the HR increases (reduced cycle lengths). Measuring the electrical restitution of the APD is thus considered to be better than only recording the APD at a fixed cycle length to assess the rate-dependence of the repolarization parameter, because it better reflects the adaptation of the repolarization time to physiological

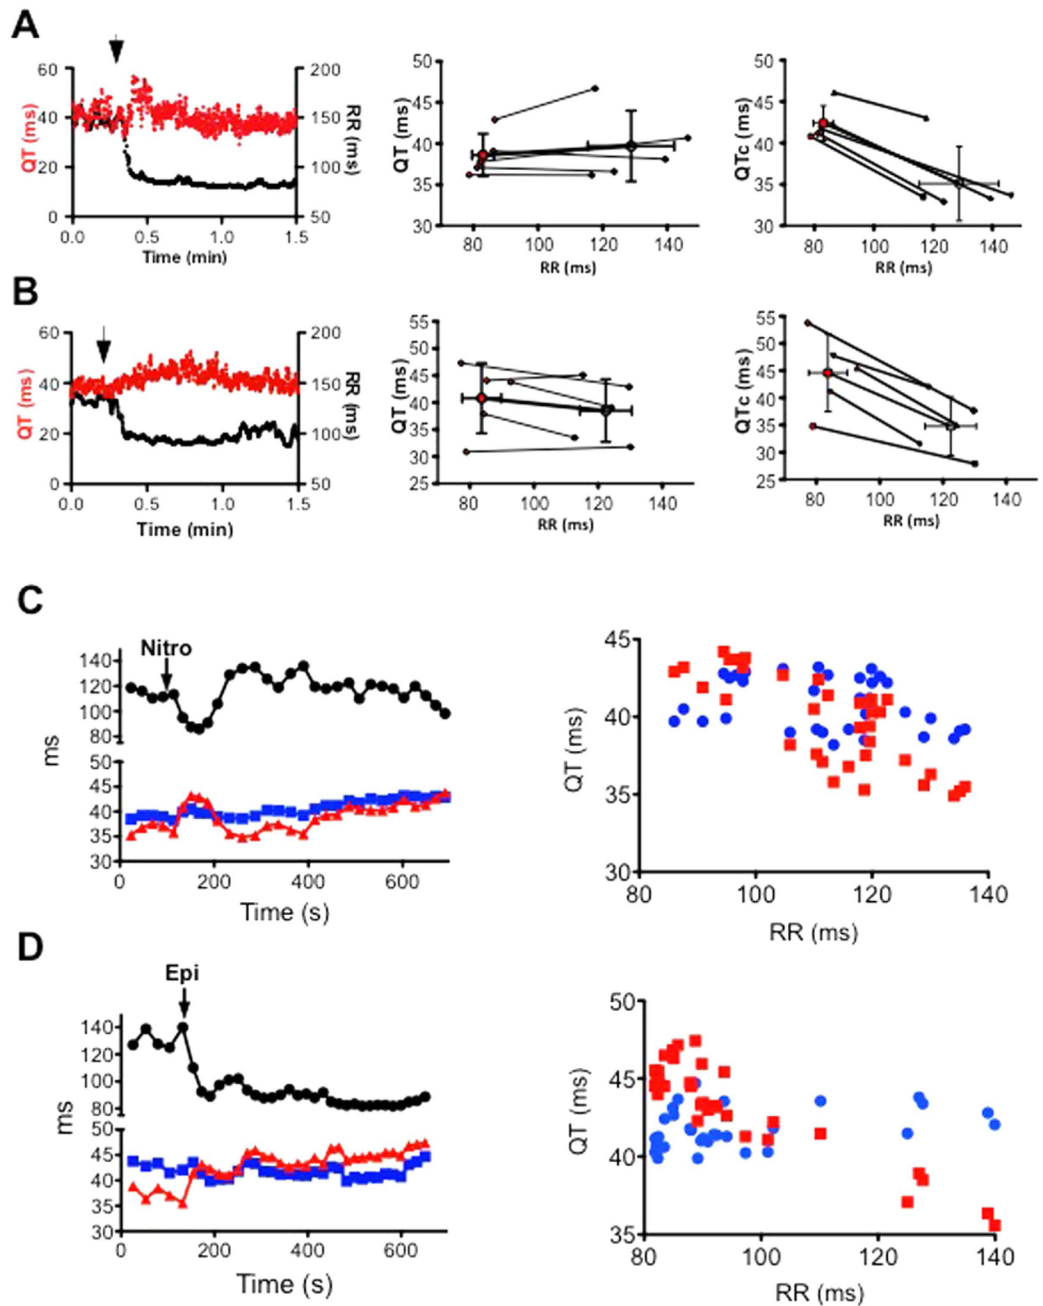

Figure 5. Influence of abrupt changes in cardiac frequency on QT interval and RR intervals in 5 mice before (black) and after (red points) IP injection of norepinephrine (A) or nitroprusside (B). Open circles give the mean RR and QT \pm SD and filled circles the individual measurements. Left, typical evolution of QT (red) and RR (black) intervals just before and in the minute following the injection; middle, raw QT-RR relationship; right, QTc-RR relationship. Evolution of the QT and QTc intervals according to the RR intervals over-time. QT (blue points), QTc (red points) and RR intervals (black points) were measured 5 minutes before and 15 minutes after injection of nitroprusside (C) or Epinephrine (D). QTc were calculated according to Mitchell's formula.

variations of the HR. Unlike what happens in humans²⁷, the APD restitution curve for late repolarization (APD₉₀) in mice is nearly flat, as elegantly shown by Knollmann and collaborators²⁸. The relative APD restitution curve for early repolarization (APD₃₀) even shortens when the stimulation interval lengthens. Accordingly, Nuyens *et al.*²⁹ have shown that a rapid change in stimulation pacing does not affect the APD₉₀ in wild-type mice. Interestingly, in the latter two studies, "steady-state" APD₉₀ measurements i.e. those measured at a fixed cycle length, exhibited stimulation rate-dependence, although this was less important than in other mammals such as dogs and humans. This phenomenon could be explained by the fact that the ionic currents determining the duration of action potentials are different in mice and humans. Potassium currents in mice do not accumulate upon repetitive stimuli but instead slowly inactivate, which explains why their action potential only moderately shortens at rapid stimulation rates³⁰.

Another explanation could also be related to the difficulty involved in accurately measuring the T wave in mice²³. Indeed, in larger animals in which the analysis of the QT is complex, electrodes have to be placed directly on the cardiac surface to be able to measure variations of the QTc in the millisecond range³¹. This aspect is important since the QT variations observed in mice are also in this range, suggesting strongly that it would be very difficult to define a QT-RR relationship using the usual methods. More work to improve methodological approaches and T-wave detection in mice and to standardize ECG-lead placements is still needed to reduce potential analytical errors during T-wave determination. In the same way, choosing an averaged RR interval to correct the averaged QT in mice, or picking a given QT instead of another based on the RR interval, could introduce a major bias in the analysis by erroneously creating a relationship between two weakly dependent variables.

Regarding our data, we propose that the lack of a QT-RR relationship is of physiological origin, since QT values were not significantly different between the diurnal and nocturnal periods, when RR values were very different. Small rodents have a rather low range of RR intervals compared to larger animals (see¹⁴). For example, Kaese & Verheule¹⁶ have reported that mice have the capacity to increase their HR by only 30–40%, compared to 300% in humans. In our study, similar results were obtained with pharmacological treatment. Under such conditions, variations in QT must be rather small, if they exist, due to the fast HR. The mouse action potential, in contrast to that of larger mammals, is short and probably acts more as a trigger for contraction, with less mechanical feedback, than in mammals that display a plateau phase in their action potential³².

Another important finding of the present study is the intra-individual variability of the QT^{16,33,34}. Indeed, for a given experiment, mean QT values are often calculated by averaging a few complexes at different time points. However, any change in QT duration might be consecutive to the physiological variation of the QT rather than to the condition tested. This information would be lost with the use of correction formulae.

In conclusion, we have demonstrated in the present study that there is no obvious QT-RR relationship in mice, and that the use of correction formulae such as those adapted from Bazett's formula would merely introduce errors.

Methods

Ethics. Ten-week-old male C57Bl/6 mice (Janvier, France) were used in this study (11 for diurnal/nocturnal study and 10 for pharmacological testing). All procedures conformed to European Parliament Directive 2010/63/EU and the 22 September 2010 Council on the protection of animals, and were approved by the institutional animal research committee (Departmental Directorate of protecting populations and animal health (ethics for animal welfare and environmental protection, N° A 34–485) and by our Ethics committee for animal experiments, Languedoc Roussillon, N° CE-LR-0714).

QT specification and determination in mice. The duration of QRS-T complexes reflects the duration of ventricular depolarization and repolarization. Due to specific electrophysiological properties at cardiomyocytes level with predominant I_{TO} current, the murine action potential lacks plateau phase. Repolarization in mice starts when another cardiac territory is not yet activated^{24–26}. Combined with the short RR interval (≈ 100 ms), the ST segment and the T-waves are difficult to identify from ECG trace, leaving some authors to suggest that T wave in mice does not exist^{24,35–37}. Nevertheless the same concepts than in human ECG are actually used for the interpretation of these rodent ECGs. Thus, several groups have tempted to empirically define the best estimation methods to define QT duration (as well reviewed in³⁸).

To date, the most used method to define the QT duration in mice is to consider the QT interval between the first deviation from an isoelectric PR interval until the return of the ventricular repolarisation to the isoelectric TP baseline, acquired by telemetry in vigil mice. This method included in the measure the low-amplitude portion of the T-wave and allows a complete ventricular repolarization of ventricles, as confirmed by a simultaneous record of monophasic ventricular action potential with ECG trace in mice³⁹. By this method the QT interval found in the literature ranges from 40 to 60 ms in unsedated mice with an RR interval comprised between 85 to 115 ms.

ECG recording and analysis. ECG were recorded using implantable TA10ETA-F10 ECG transmitters (Data Sciences International). Mice were instrumented under general gaseous anesthesia (2–2.5% isoflurane/O₂, Aerrane). The transmitter device was inserted subcutaneously along the back, and the two ECG electrodes were placed subcutaneously in the region of the right shoulder (negative lead) and toward the lower left chest (positive lead) to approximate lead II of the Einthoven surface ECG. Measurements were performed 2 weeks after total recovery from surgery, which allows retrieving complete HR variability i.e. a normal regulation of heart rhythm by autonomic nervous system⁴⁰. Mice were then monitored with ECG recordings in their home cage with a signal transmitter-receiver (RPC-1) connected to a data acquisition system (Physiotel, Ponemah software, Data Sciences International). ECG were collected continuously over 24 h at a sampling rate of 2000 Hz in a dedicated room with respect to diurnal-nocturnal variations (12h/12h cycle), controlled hygrometry and temperature. Mice have access *ad libitum* to water and feed. Continuous 30 minutes digital recordings obtained during nocturnal period, i.e. during activity phase, were analyzed off line with Ponemah software, 3 hours after the turn on or up of the lights. At least 10.000 PQRST cycles, exclusively during sinus rhythm, were analyzed per condition. QRS complexes from ventricular extrasystoles, premature ventricular contractions or atrio-ventricular blocks were systematically rejected for the analyses. The good identification of ECG waves by the software and the good positioning of the cursors were validated “beat to beat” or modified by operator if needed (<5%). QT duration was defined as the interval between the first deviation from the isoelectric PR interval (Q wave) until the return of the ventricular repolarization to the isoelectric TP baseline from lead II ECGs. If one doubt existed due to the lack of stable isoelectrical line, an abnormal morphology of PQRST waveform, or chaotic electrical noise due to movement artifact, the PQRST sequence was not included in the analysis until next valuable complexes. When

correction formula was applied, each QT was corrected to its own RR interval measured between two consecutive PQRST complexes, no average of RR intervals was performed to correct QT interval.

To test the strength of QT measurement and QT correction over a same mice, QT intervals were also measured over at least 200 consecutive QRS complexes randomly picked each 20 minutes over one hour (according to their good detection as mentioned earlier), and QT was corrected with the formula of Mitchell¹⁹:

$$QT_c = \frac{QT}{\sqrt{\frac{RR}{100}}} \quad (1)$$

Pharmacology. To study the relationship between the QT interval and cardiac frequency, we used two different approaches. The first one consisted in the measurement and analysis of RR and QT during nocturnal periods (high activity periods in mice) and during diurnal periods (periods of rest for mice). Beside these physiological changes in cardiac frequency, we also injected intraperitoneously 1 mg.kg⁻¹ epinephrine or 1 mg.kg⁻¹ nitroprusside in diurnal periods to trigger tachycardia by two different pathways. With epinephrine, the tachycardia is consecutive to the β -adrenergic activation at the sinus level while with nitroprusside, it is consecutive to the hypotension induced by the drug (baroreflex activation). Measurements were performed five minutes before and fifteen minutes after dosing.

Epinephrine and nitroprusside were obtained from Sigma-Aldrich (Grenoble, France).

Statistics. Analysis and graphs were produced thanks to Prism[®]. Pearson's r correlation was determined for each QT-RR plots during the diurnal and the nocturnal periods. To compare the mean QT and RR during the diurnal or nocturnal periods, a paired student t-test was used. In all cases, $p < 0.05$ was considered as significant.

Acknowledgements

J. Roussel was supported by the “Groupe de Réflexion sur la Recherche Cardiovasculaire (GRRC)”. The work was supported by the Fondation de France (Synaptocard project, No. 2013-00038586). We thank Dr S. Rasika of *Gap Junction* (www.gap-junction.com) for assistance with English editing.

Author Contributions

Ju.R. and Je.R. performed experiments and wrote the manuscript. P.C. assisted with the design of the study and wrote the manuscript. S.R. and J.F. wrote the manuscript. J.-Y.L.G. assisted with the design of the study, analyzed data and wrote the manuscript. J.T. assisted with the design the study, performed experiments, analyzed data and wrote the manuscript.
