The behavior of Pu(IV) and Pu(III) was investigated in aqueous nitric solutions under ultrasound irradiation (Ar, 20 kHz). In the absence of anti-nitrous reagents, ultrasound has no effect on Pu(IV), while Pu(III) can be rapidly oxidized to Pu(IV) due to the autocatalytic formation of HNO₂ induced by HNO₃ sonolysis. In the presence of anti-nitrous reagents (sulfamic acid or hydrazinium nitrate), Pu(IV) can be sonochemically reduced to Pu(III). The reduction follows a first order reaction law and leads to a steady state where Pu(IV) and Pu(III) coexist in solution. The reduction process is attributed to the sonochemical generation of H₂O₂ in solution. The kinetics attributed to the reduction of Pu(IV) are however higher than those related to the formation of H₂O₂ which, after several hypotheses, is explained by the sonochemical erosion of the titanium-based sonotrode. Titanium particles thereby generated can be solubilized under ultrasound and generate Ti(III) as an intermediate species, a strong reducing agent able to react with Pu(IV).

Introduction

H₂O₂ has been an interesting and powerful salt-free reagent for industry. It is cheap, available in large and pure quantities, and yields volatile oxidation species that do not interfere with final reaction products. Despite its radiolysis-induced occurrence, hydrogen peroxide has been considered to be a chemical of paramount importance in actinide chemistry and nuclear processing because of its acido-basic, redox, and

complexing properties.^{1,2} Besides its other advantages, using H₂O₂ in large scale chemistry allows avoiding dilution of treated solutions which is particularly important in actinide chemistry, where the control of hydrolysis and concentration of target elements is often challenging.¹ These attributes have been widely used for the purification, separation and oxidation state adjustment of several actinide elements, including Pu, U, and Np.¹⁻⁵ Indeed, H₂O₂ can be considered as both an oxidizing (1.77 V vs. SHE) and reducing (0.68 V vs. SHE) species.

For instance, the addition of H₂O₂ to Pu(VI) solutions has been routinely used to obtain and stabilize Pu(IV) aqueous nitric solutions prior to anion exchange separation and oxalate precipitation.¹⁻⁴ In nitric media, the reduction of Pu(VI) with H₂O₂ occurs through Pu(V) formation which can also be thermodynamically reduced to Pu(IV). However, Pu(IV) accumulation is generated through Pu(V) dismutation because of its strong proton dependency and the higher kinetics required to break oxo bonds.^{1,6,7} Hydrogen peroxide can also be used for the reduction of Pu(IV), leading to Pu(III) or to a steady state composed of Pu(IV) and Pu(III) in various proportions.^{1,3,8,9} The shifting of this ratio is highly dependent upon the experimental conditions such as the temperature, acidity, counter-ion, or reactant concentrations. Pu(IV) reduction results from the formation of peroxy complexes that decompose in acidic media.^{2,8-11} Using these conditions, plutonium may therefore be considered as a decomposition catalyst for H₂O₂.

Ultrasound propagation in aqueous solutions offers the possibility of generating *in situ* redox species under relatively mild conditions. This effect is not attributed to direct interactions of ultrasound waves with molecules, but rather from acoustic cavitation, which is the nucleation, growth, and rapid implosive collapse of vapour filled micro-bubbles.¹²⁻¹⁴ At collapse, these micro-reactors may lead to the formation of chemical species able to react in the treated bulk solution. For instance, the sonolysis of pure water under an Ar atmosphere causes the homolytic dissociation of H₂O molecules according to reactions (1)–(2) and generates radical species, leading, after recombination, to the accumulation of hydrogen peroxide in the solution and release of molecular H₂ in the gaseous flow.¹⁴ The formation rates follow zero-order kinetics and strongly depend upon the sonochemical conditions such as the ultrasound frequency, acoustic power, temperature, or gaseous atmosphere. Indeed, the 20 kHz sonication of pure water under Ar at 20 °C leads to a sonochemical yield of

H₂O₂ formation of 0.06 μmol kJ⁻¹ while 0.46 μmol kJ⁻¹ are measured at 607 kHz using similar conditions.¹⁵

In aqueous nitric solutions, accumulation of H₂O₂ is not observed due to the formation of nitrous acid which rapidly reacts with hydrogen peroxide (eqn (3)).¹⁶ The addition of anti-nitrous reagents such as sulfamic acid, hydrazinium nitrate, or urea to the medium avoids the accumulation of HNO₂ and therefore enables the presence of H₂O₂ in solution. Previous investigations showed that the accumulation rate of hydrogen peroxide observed during the sonication of aqueous nitric solutions is higher than what was observed in pure water.^{13,17} The formation rate observed for H₂O₂ at 22 kHz and 24 °C in 1 M HNO₃ (in the presence of anti-nitrous reagent) was indeed found to be approximately 2.4 times higher than what was observed in pure water under similar conditions. This phenomenon results from a different mechanism of formation for H₂O₂ where HO[°] reacts with nitrate ions to generate NO[°]₃ which leads to H₂O₂ after hydrolysis (eqn (4)–(5)).^{13,17} In this mechanism, only one hydroxyl radical is used to produce one hydrogen peroxide molecule whereas two hydroxyl radicals are required in pure water (eqn (2)). Note that in heterogeneous systems, the implosive collapse of acoustic bubbles in the vicinity of extended surfaces is able to favour the fragmentation of particles and the erosion of surfaces. An increase of the mass transfer is also reported.¹⁴

The adjustment of the actinide oxidation state in recycling processes of spent nuclear fuel (e.g. PUREX) is important for their recovery and separation necessarily performed with very high yields.^{1-3,18,19} The industrial addition of chemicals in recycling processing of nuclear fuel poses the question of wastes and effluent management in

addition to the already existing safety limitations. High-power ultrasound offers the opportunity to generate *in situ* redox species with controlled kinetics and therefore suggests the possible application of ultrasound in actinide chemistry.¹³ Since the first investigations devoted to the chemical influence of ultrasound irradiation on actinides, only a few studies have been reported in the literature. Mainly, the studies dealt with the dissolution of oxides²⁰⁻²² and the valency control of actinide ions in aqueous solutions.²³⁻²⁶ Note that more recently, the sonochemical excitation of uranyl ions has been demonstrated in sonoluminescence studies.²⁷ The aim of the present work is to evaluate the influence of ultrasound on the redox behavior of Pu(IV) and Pu(III) in aqueous nitric solutions. For this study, sonochemical set-ups have been developed in a “hot” glove box in the Atalante facility (CEA Marcoule). The experiments were performed under Ar bubbling at 20 kHz at almost ambient temperature.

Experimental section

Caution! Pu is an α -emitting element presenting serious health risks. Studies dealing with such an element require a careful handling coupled with appropriate infrastructures and trained workers.

Materials

Stock solutions of Pu(IV) (~96.9% ²³⁹Pu) in nitric acid were prepared by dissolving PuO₂ powder in concentrated nitric acid with HF aliquots. The resulting solution was concentrated and purified in nitric media on a chromatographic column filled with a DOWEX anion exchange resin to remove impurities arising from Pu decay. Plutonium stock solution was then adjusted to its (+IV) oxidation state using H₂O₂ aliquots. Before investigations, the solution was characterized by determining the Pu concentration and the acidity of the solution (Radiometer titralab TIM865, electrode Radiometer XC161), and was stored in a lead castle until use. All the chemicals used were of analytical grade and were purchased from Sigma Aldrich. The various solutions were prepared using purified ultrapure water having a resistivity higher than 18.2 M Ω cm (25 °C).

Sonochemical experiments

Active experiments were performed in the ATALANTE facility (Marcoule) in a glove box devoted to investigations dealing with sonochemical reactions of actinide elements in various chemical systems. The negative pressure glove box is equipped with thermostated “cup horn” tight reactors (50 or 100 mL) connected to a Lauda E210 cryostat from the outside of the enclosure. Note that the cooling system is

equipped with a heat exchanger for avoiding a potential Pu contamination. A thermocouple inserted into the reactor allowed the control of the temperature which was maintained at 25–30 °C during sonication experiments. Specific “non-active” experiments were performed at the ICSM facility (Marcoule) in a home-made reactor with an immersed probe already described in the literature.^{28,29} Sonochemical experiments were performed using 20 kHz ultrasonic processors purchased from Bioblock Scientific (Vibracell, 600 W, ATALANTE) and from Sonics & Materials (Vibracell, VCX 750, ICSM). The devices consist of a piezoelectric transducer coupled with a titanium horn of 1 (for the plunging probe), 7.9, or 18.1 cm² (for the inversed “cup-horn” transducers).

The cells consist of Teflon rings, ensuring reproducible airtight experiments. Sonochemical experiments were performed under Ar, which was bubbling (100 mL min⁻¹) through the solution 20 min before starting sonication and was maintained during the whole experiment. In agreement with the literature, the sonochemical reaction rates are driven by the absorbed acoustic energy.³⁰ Therefore, to compare accurately the results obtained with the different geometries, the specific acoustic power (W mL⁻¹) delivered to the solution was determined and assessed by the thermal probe method in agreement with the literature and the following [eqn \(6\)–\(7\)](#):

$$P(W) = mC_p \left(\frac{dT}{dt} \right)_{t=0}$$

$$P_{ac} (W \text{ mL}^{-1}) = \frac{P}{V}$$

with m the mass of the treated water, C_p the specific heat capacity of water at room temperature and pressure (4.18 J kg⁻¹ K⁻¹), and V the volume of the sonicated solution (mL). $(dT/dt)_{t=0}$ is the initial slope of the temperature variation of the solution against time under ultrasound irradiation. A detailed description of the geometric and calorimetric comparison between the different sonochemical reactors might be found in the literature for previous investigations.³⁰

UV-Vis spectrophotometry

UV-Vis spectrophotometry analyses were directly recorded inside the glove box through optic fibers allowing the measurement of the solutions from 350 to 900 nm (Shimadzu UV3600 spectrometer). Pu(IV) was followed at ~476 nm ($\epsilon = 73 \text{ cm}^{-1} \text{ M}^{-1}$) while Pu(III) was followed at ~602 nm ($\epsilon = 33 \text{ cm}^{-1} \text{ M}^{-1}$). Concentration variations were determined by measuring the “peak-valley” difference in absorbance. The reported extinction and apparition rates for Pu(IV) and Pu(III) were established by tracing the initial slope of the corresponding kinetic curves for ca. 90 min and were given as $W_0(-\text{Pu}^{\text{IV}})$ and $W_0(\text{Pu}^{\text{III}})$, respectively. Note that slight uncertainties may be pointed out for measurements due to the optic fibers used, particularly for Pu(III) which displays in addition a low extinction coefficient. The formation of hydrogen

peroxide resulting from the homolytic dissociation of sonicated water molecules was measured by a spectrophotometric method. The procedure consists in diluting aliquots of the sonicated media (pure water or aqueous nitric solution) with a solution made of 2×10^{-2} M TiOSO_4 in 0.5 M HNO_3 –0.01 M $[\text{N}_2\text{H}_5][\text{NO}_3]$. The formation of a stable $\text{Ti(IV)}\cdot\text{H}_2\text{O}_2$ complex is then followed at $\lambda_{\text{max}} = 410$ nm ($\epsilon = 730$ cm^{-1} M^{-1}).³¹ The detection limit of the method is $\sim 3 \times 10^{-5}$ M. The potential formation of hydroxylammonium nitrate during sonolysis was followed by a colorimetric method using the ferrozine procedure. The operation consists in reducing Fe(III) with hydroxylamine to generate Fe(II) which react with the ferrozine salt 3-(2-pyridyl)-5,6-diphenyl-1,2,4-triazine-*p,p'*-disulfonic acid disodium salt to produce a purple complex measured at $\lambda_{\text{max}} = 560$ nm ($\epsilon = 35\,000$ cm^{-1} M^{-1}).^{31,32} The detection limit of the procedure is $\sim 4 \times 10^{-6}$ M.

ICP-OES measurements

The concentration of titanium in inactive solutions was determined by inductively coupled plasma optical emission spectroscopy (ICP-OES) using a Spectro Arcos device supplied by Spectro Analytical Instruments GmbH and equipped for axial plasma observation (for inactive experiments). Filtered aliquots (0.2 μm PTFE filters from VWR) of the treated solution were diluted with 0.3 M HNO_3 to obtain a $\sim 2\%$ acidified solution. The resulting samples were analyzed against an external calibration curve prepared with certified Ti standard solutions (SCP Science, Courtaboeuf, France). The repeated measurements of these samples during analyses allowed determining standard deviations. The detection limit is ~ 0.1 ppm.

MS measurements

Mass spectrometry (MS) was used to evaluate the H_2 formation during sonolysis under inactive conditions. Measurements were made with a quadrupole mass spectrometer (Prolab 300, Thermo Fisher). The water vapor potentially generated during sonolysis was trapped using 3 Å molecular sieves (Sigma-Aldrich) prior to mass spectrometry experiments.

Results and discussion

In the absence of anti-nitrous reagents, preliminary investigations revealed that aqueous nitric solutions of Pu(IV) are chemically stable under ultrasound irradiation in agreement with the literature.^{24,25,31} By contrast, the sonolysis of an equivalent Pu(III) solution leads to the rapid accumulation of Pu(IV) . The reaction mechanism involves the *in situ* generation of nitrous acid and NO_x molecules from HNO_3 sonolysis.^{13,16,28} It results from the thermolysis of non-dissociated HNO_3 molecules within the acoustic bubbles and nitrate ions at the liquid reaction zone surrounding the bubbles ([eqn \(8\)–\(9\)](#)). Pu(III) oxidation with HNO_2 is rapid and autocatalytic as illustrated by the reactions [\(8\)–\(12\)](#). Secondary reactions may also occur with NO_2 in agreement with

the reaction (13). In this system, the generation of HNO₂ avoids the accumulation of H₂O₂ from water sonolysis (eqn (1)–(2)) due to the rapid reaction of both species according to the reaction (3) already described in the Introduction.^{13,16}

In the presence of 0.1 M sulfamic acid as an anti-nitrous reagent (eqn (14)), the sonolysis of a Pu(IV) solution in 1 M HNO₃ leads to a significant decrease of Pu(IV) concentration followed at 476 nm. Simultaneously, the generation of Pu(III) is observed at 602 nm as illustrated by the selected UV-Vis spectra in Fig. 1. The evolution of the corresponding Pu concentrations measured in solution as a function of the sonication time is plotted in Fig. 2 for different acoustic powers. The observation of both Fig. 1 and 2 evidences the simultaneous existence of Pu(III) and Pu(IV) in solution. For an acoustic power of 0.26 W mL⁻¹, the initial extinction and accumulation rates observed for Pu(IV) and Pu(III), respectively, are equivalent and linear: $W_0(-\text{Pu}^{\text{IV}}) = 7 \mu\text{M min}^{-1}$ and $W_0(\text{Pu}^{\text{III}}) = 8 \mu\text{M min}^{-1}$ (Fig. 2(a)). When the acoustic power reaches 0.38 W mL⁻¹, the reaction rates are dramatically enhanced to $W_0(-\text{Pu}^{\text{IV}}) = 17 \mu\text{M min}^{-1}$ and $W_0(\text{Pu}^{\text{III}}) = 22 \mu\text{M min}^{-1}$.

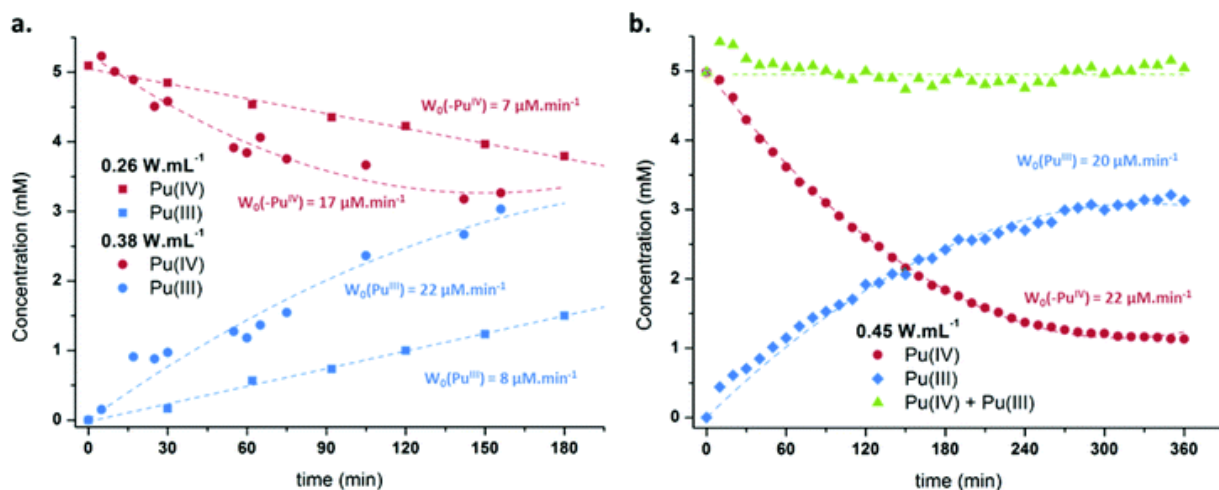

Fig. 2 Sonolysis (20 kHz, Ar, 25–29 °C) of Pu(IV) in 1 M HNO₃ in the presence of 0.1 M NH₂SO₃H at (a) 0.26, 0.38, and (b) 0.45 W.mL⁻¹.

Fig. 1 UV-Vis absorption spectra observed during the sonolysis (20 kHz, Ar, 25–29 °C) of Pu(IV) in 1 M HNO₃ in the presence of 0.1 M NH₂SO₃H.

Although equivalent to each other, Pu(IV) and Pu(III) rates are no more linear and are fitted with polynomial functions. Note that the slight rate difference observed between Pu(IV) and Pu(III) results from an uncertainty provided by the low extinction coefficient of Pu(III) coupled with the optic fibers used for UV-Vis measurements. With increasing again the delivered acoustic power to 0.45 W mL⁻¹ (Fig. 2(b)), the initial rate of extinction observed for Pu(IV) is about 22 μM min⁻¹ while the initial rate of accumulation reported for $W_0(\text{Pu}^{\text{III}})$ reaches 20 μM min⁻¹. In agreement with Fig. 2(a), this observation evidence the occurring relationship between the increases of

Pu(IV) extinction rate and the delivered acoustic power. Note however that the reaction is not complete whatever be the acoustic power and leads, for prolonged sonication, to a steady state where Pu(III) and Pu(IV) coexist in solution.

In these sonicated solutions, the presence of sulfamic acid involves the rapid scavenging of HNO₂ formed during sonolysis according to [eqn \(14\)](#), thus avoiding the completion of the reaction [\(3\)](#).¹⁶ This scavenger offers two advantages: it avoids the back-oxidation of Pu(III) with HNO₂ when reduced, and allows in the meantime the quantitative accumulation of H₂O₂ in nitric solution. However, in the presence of Pu(IV), H₂O₂ was not observed, most probably because of its consumption in the Pu reduction process. In addition, other Pu valencies such as Pu(VI) or Pu(V) were not detected in the various sonicated solutions as evidenced by UV-Vis spectrophotometry and the total Pu content expressed by the green triangle plots in [Fig. 2\(b\)](#) (not shown in [Fig. 2\(a\)](#) for clarity of the picture). In consequence, Pu(III) accumulation in the sonicated solutions can be attributed to the reduction of Pu(IV) resulting from the *in situ* generation of hydrogen peroxide during sonication.

Without ultrasound, this redox reaction has been widely studied for Pu solution stabilization and/or purification in nitric media. The reaction is reversible and leads to a steady state which is strongly dependent upon reagent concentrations and acidity.^{1,3,7-9} This steady state is supposed to result from the simultaneous back-oxidation of Pu(III) to Pu(IV) by hydrogen peroxide in agreement with the redox potentials of Pu(IV)/Pu(III) ($E^\circ = 0.91$ V vs. SHE) and H₂O₂/H₂O ($E^\circ = 1.77$ V vs. SHE) couples.¹¹ This assertion has been successfully verified in our system by sonicating a Pu(III) solution in an aqueous nitric solution in the presence of hydrazinium nitrate as an anti-nitrous reagent (Fig. S1, ESI[†]). It is also noteworthy that Pu(III) accumulation is supposed to occur from the decomposition of a soluble Pu(IV) peroxy complex which follows a first order rate law according to the reactions [\(15\)–\(16\)](#).^{2,7-11} These peroxides (usually observed at 495, 540, or 513 nm with relatively high extinction coefficient) were not detected in our solutions, probably because of their low amount and instability in acid media, which can be possibly intensified under ultrasound irradiation. The sonochemical reduction of Pu(IV) follows a first-order reaction law in agreement with Fig. S2, ESI[†]. Under these conditions, the measured apparent rate

constant is $\sim 5.7 \times 10^{-3} \text{ min}^{-1}$. In accordance with the previous observations and the literature, the overall reaction scheme of Pu ions in the sonicated system may be described by [eqn \(17\)–\(18\)](#).^{8–11}

In order to compare Pu reduction with H_2O_2 formation rates, similar experiments were performed in the absence of Pu ions to allow H_2O_2 accumulation in solution. The sonochemical kinetics determined under similar experimental conditions are shown in [Table 1](#). In agreement with the above results and the literature, $W_0(-\text{Pu}^{\text{IV}})$, $W_0(\text{Pu}^{\text{III}})$ and $W_0(\text{H}_2\text{O}_2)$ increase with rising acoustic power P_{ac} .¹⁴ As illustrated by [Fig. 2](#), $W_0(-\text{Pu}^{\text{IV}})$ and $W_0(\text{Pu}^{\text{III}})$ exhibit equivalent rates whatever the experiment which emphasizes the relationship occurring between Pu(IV) and Pu(III). However, these kinetics also reveal that Pu(IV) is reduced faster than H_2O_2 is generated whatever be P_{ac} . The stoichiometric equation [\(17\)](#) cannot completely explain the reduction of Pu(IV) in this system; the mechanism of reduction appears to exhibit a complementary reduction step not explained by the sole reaction with H_2O_2 . Note also that the calculated ratio $W_0(-\text{Pu}^{\text{IV}})/W_0(\text{H}_2\text{O}_2)$ increases with the delivered acoustic power, indicating that this phenomenon is influenced by the acoustic cavitation. By plotting $W_0(-\text{Pu}^{\text{IV}})$ as a function of P_{ac} , a threshold value of 0.17 W mL^{-1} may be graphically established indicating the minimal acoustic power required to observe sonochemical Pu(IV) reduction ([Fig. S3, ESI†](#)). This value is very close to the 0.18 W mL^{-1} threshold acoustic intensity (9 W cm^{-2} for 50 mL with a 1 cm^2 tip) reported in the literature when measuring HO° generation under 22 kHz ultrasound.³³ This observation also emphasizes the already proposed reduction mechanism occurring with H_2O_2 , a recombination product of HO° radicals.

Table 1 Comparison of the sonochemical kinetics (Ar, 20 kHz , $V = 50 \text{ mL}$, $0.26\text{--}0.45 \text{ W mL}^{-1}$) observed in $1 \text{ M HNO}_3\text{--}0.1 \text{ M NH}_2\text{SO}_3\text{H}$ for Pu(IV) reduction and H_2O_2 accumulation

$P_{ac} = \frac{W_0(H_2O_2) - W_0(-Pu^{IV}) - W_0(Pu^{III})}{W_0(-Pu^{IV})/W_0(H_2O_2)}$
 $W_0(H_2O_2)$ ($\mu M \min^{-1}$) $W_0(-Pu^{IV})$ ($\mu M \min^{-1}$) $W_0(Pu^{III})$ ($\mu M \min^{-1}$) $W_0(-Pu^{IV})/W_0(H_2O_2)$

a Note that the precision for this experiment was particularly low and this results from the optic fibers and the low molar extinction coefficient of Pu(III). This problem can be observed in [Fig. 2\(a\)](#) only.

0.26	2.7	7	8	2.6
0.38	5.5	17	22 ^a	3.1
0.45	6.3	22	22	3.5

In order to evaluate the influence of the anti-nitrous reagent on reduction kinetics, sulfamic acid was replaced by hydrazinium nitrate, $[N_2H_5][NO_3]$. [Fig. 3\(a\)](#) illustrates the evolution of selected UV-Vis absorption spectra for a sonicated solution (20 kHz, Ar, $0.52 W mL^{-1}$, $V = 50 mL$) of 5 mM Pu(IV) in 1 M HNO_3 –0.1 M $[N_2H_5][NO_3]$. The spectra evidence a simultaneous decrease of Pu(IV) concentration at 476 nm coupled with the growth of Pu(III) at 602 nm in agreement with [Fig. 1](#) and [2](#). The corresponding plotted data for Pu concentrations in this system are illustrated in [Fig. 3\(b\)](#). In agreement with the results reported in sulfamic media ([Fig. 2](#)), the initial rates of reduction for Pu(IV) and accumulation for Pu(III) are equivalent ($27 \mu M \min^{-1}$). The kinetic curves exhibit an exponential decrease consistent with a first reaction order (apparent rate constant of $7.5 \times 10^{-3} \min^{-1}$) leading to a steady state shifted toward Pu(III) formation (ESI, [Fig. S4](#)). Analyses evidenced the absence of hydrogen peroxide in solution during sonolysis which emphasizes again the predominant role of H_2O_2 in Pu(IV) reduction. Furthermore, the total concentration of plutonium is consistent during sonolysis, indicating that no extra valency state of Pu is generated during Pu(IV) reduction.

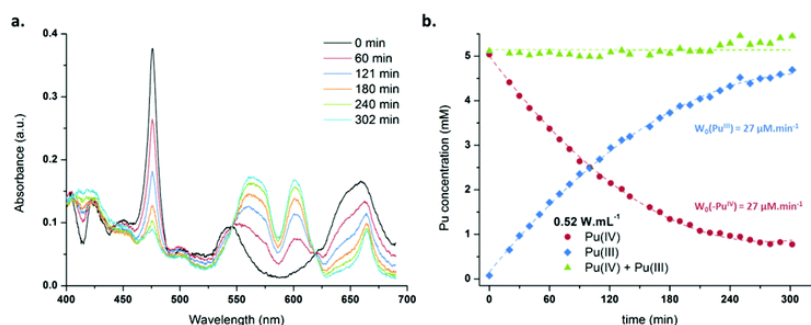

Fig. 3 (a) UV-vis absorption spectra and (b) the corresponding plotted data observed during the sonochemical reduction of Pu(IV) in 1 M HNO_3 in the presence of 0.1 M $[N_2H_5][NO_3]$ at $0.52 W mL^{-1}$.

The initial rates observed for Pu(IV) reduction and Pu(III) accumulation however present higher values than what was observed in the presence of sulfamic acid. This phenomenon results from the presence of hydrazinium nitrate which is known to be a reducing agent for Pu(IV).^{1,34} The reaction (19) characterizes the limitedly occurring process with an excess of hydrazinium nitrate. The reduction rate of Pu(IV) attributed to the presence of [N₂H₅][NO₃] can be independently measured in order to evaluate the kinetics only attributed to ultrasound in this system in agreement with the following formula (20):

$$W_0(-\text{Pu}^{\text{IV}})_{\text{US}} = W_0(-\text{Pu}^{\text{IV}})_{\text{US+NH}} - W_0(-\text{Pu}^{\text{IV}})_{\text{NH}}$$

Pu(IV) reduction was therefore studied in 1 M HNO₃–0.1 M [N₂H₅][NO₃] under silent conditions, *i.e.* under stirring with the other experimental conditions being equal. Fig. 4 illustrates the various kinetics observed for Pu(IV) in the presence and absence of ultrasound; the same picture completed with Pu(III) data may be found in the ESI, Fig. S5.† The initial rate of reduction for Pu(IV) attributed to the sole presence of hydrazinium nitrate (eqn (19)) reaches 6 μM min⁻¹ (and 7 μM min⁻¹ for Pu(III) accumulation). The reduction with [N₂H₅][NO₃] follows a first order reaction law with an apparent rate constant of ~1.3 × 10⁻³ min⁻¹. By subtracting the corresponding reduction curve to the one measured during the sonolysis of the same solution (W₀(-Pu^{IV})_{US+NH}), Pu(IV) reduction attributed to H₂O₂ generation can be deduced (red curve) and the initial rate of reduction can be measured for this system: W₀(-Pu^{IV})_{US} = 22 μM min⁻¹. The deduced reduction rate agrees with previous observations (Fig. 2) and can be compared to W₀(H₂O₂) observed under the same conditions (*i.e.*, in the absence of Pu in solution in order to accumulate H₂O₂). In agreement with what was observed in the presence of sulfamic acid, Pu(IV) reduction occurs faster than H₂O₂ is produced (a formation rate of 5.3 μM min⁻¹ was observed under these conditions); the observed kinetics cannot be solely explained by the stoichiometry of the reactions (17)–(18). As was shown above in the presence of sulfamic acid, the reaction assumes an additional reduction step not explained by the sole generation of hydrogen peroxide.

Fig. 4 Reduction of Pu(IV) under stirring or ultrasound (20 kHz, Ar, 0.52 W mL⁻¹, 26 °C) in 1 M HNO₃-0.1

Note that redox reactions involving plutonium ions and sonochemically-produced radical species (HO°, NO₃°, H°, *etc.*) could also be considered. However, these radicals mostly recombine inside the bubble and their reactions with species from the bulk or the bubble interface are considered to be lower and limited by the fact that ions cannot diffuse inside the bubble. On the other hand, the quantity of radicals diffusing from the bubble to the solution is known to be very small; the contribution of direct radical mechanisms is therefore expected to be negligible in comparison to the reactions occurring with radical recombination products such as H₂O₂ or H₂.

Nevertheless, several hypotheses were proposed to explain the kinetic discrepancies observed during the sonochemical reduction of Pu(IV) in comparison to the related accumulation rate of H₂O₂. For instance, H atoms and molecular H₂ are good reducing agents that can be generated from aqueous solution sonolyses. On-line mass spectrometry was used to determine the continuous generation of H₂ in solution during sonication. Experiments revealed that the formation of H₂ in 1 M HNO₃ (with or without anti-nitrous reagent) was even lower than is generally reported in pure water sonolysis using the same conditions. Nitrates and nitrites are indeed known to be very good H atom scavengers, therefore avoiding the generation of molecular H₂ in this sonicated system in agreement with [eqn \(21\)–\(22\)](#).^{13,17,35,36}

Hydroxylammonium nitrate is known to be an effective reducing agent for Pu(IV). In principle, the sonolysis of nitric acid in the presence of anti-nitrous reagents used in this work could lead to the formation of hydroxylamine intermediate as shown in the ESI.† UV-Vis spectrophotometry and ion chromatography were used to determine the possible generation of this species during sonolyses. Both techniques revealed the absence of hydroxylamine in the sonicated solutions.

Finally, investigations showed that the prolonged sonication of Pu solution involved significant accumulation of visible grey Ti particles in solution. This effect results from the implosive collapse of acoustic bubbles in the vicinity of extended solid surfaces.^{14,37,38} At collapse, concerted micro-jets and shock waves provoke the erosion of surfaces. The following depassivation and fragmentation of particles enhanced by the increase of mass transfer may favor solubilization. Sonotrode tips made of titanium alloy may therefore erode and liberate Ti particles in solution. After 0.2 µm filtration, ICP-AES evidenced the presence of Ti in sampled solution as a function of the sonication time (Fig. 5). In this system, the Ti accumulation rate was found to have the same magnitude order as the one observed during Pu(IV) reduction. Considering that Ti⁰ dissolution in HNO₃ medium involves the formation of Ti(III) as an unstable intermediate and TiO²⁺ as a final product, one can assume that at least some part of Ti(III) (*E* ~ 0 V vs. SHE) may participate in Pu(IV) reduction. This species has already been used for PuO₂ reductive dissolution in non-nitric medium.^{22,39} The additional reduction kinetics observed in the sonicated Pu solution may in consequence be attributed to the presence of Ti particles in solution in agreement with the following reaction scheme (23)–(24).

Fig. 5 Titanium (mM) determination (ICP-AES) as a function of sonication time in 1 M HNO₃ with or without NH₂SO₃H. The black dashed lines are the linear fit of the observed data, and the surrounding lines are assigned to their relative confidence limits. The insert shows pictures of a titanium tip before and after several hours (8–10 h) of sonication.

Titanium and its alloys are well known for their high corrosion resistance because of the formation of an insoluble oxide layer on their surface. Ti particles observed using our conditions should be highly passivated in nitric solution; however, the application of ultrasound irradiation significantly contributes to the depassivation and/or solubilization of these particles. Note also, in [Fig. 5](#), the lower accumulation rate observed for Ti in 1 M HNO₃ in the presence of sulfamic acid. This probably results from a better solubilization of Ti particles in the presence of nitrous acid and NO_x generated under ultrasound. The influence of titanium in this chemical system was also emphasized by preparing filtered and non-filtered aliquots of Pu solutions after prolonged Pu sonolyses. The comparison of these aliquots after several days showed the dramatic decrease of Pu(IV) concentration and increase of Pu(III) for the non-filtered solution while the filtered aliquot evolved only slightly with time ([Fig. 6](#)). This slight variation may be attributed to the presence of smaller Ti particles not retained on the filter. This observation indicates that Ti particles may also directly participate in Pu(IV) reduction probably *via* the reaction at the interface.

Fig. 6 Evolution of the Pu(III)/Pu(IV) ratio in filtered and non-filtered solutions after sonolysis (20 kHz, Ar, $\text{NH}_2\text{SO}_3\text{H}$).

Conclusion

This study demonstrates the potential of ultrasound to control the oxidation state of actinides in solution. The sonochemical reduction of Pu(IV) to Pu(III) can be observed in diluted nitric solutions in the presence of anti-nitrous reagents. The reduction reaction occurs through the *in situ* generation of H_2O_2 according to a first order reaction law and leads to a steady state where Pu(IV) and Pu(III) coexist in solution. The initial reaction rate is highly a function of the delivered acoustic power, and the observed kinetics discrepancies can be attributed to the accumulation and subsequent solubilization of Ti particles produced from the ultrasonic probe erosion. Sonochemistry offers an opportunity to generate *in situ* redox species without adding any chemicals, which could be appropriate in nuclear processing, where diminishing the quantity of waste and effluents is of particular interest. The yields reported in this study should be dramatically increased in future investigations by adjusting the saturating gas and ultrasonic frequency. Once adapted to the large scale, ultrasound irradiation could offer a suitable kinetic control for Pu stabilization, thus avoiding the formation of peroxy-complexes sometimes encountered in nuclear processing.
