End-Member Analysis

A B S T R A C T

Qualitative and quantitative changes of organic and carbonate carbon in sedimentary records are frequently used to reconstruct past environments, paleoproductivity and sediment provenance. Amongst the most commonly used proxies are Total Organic Carbon (TOC), Mineral Carbon (MinC), as well as Hydrogen (HI) and Oxygen Indices (OI) of organic matter (OM). Rock Eval pyrolysis enables the assessment of these quantitative and qualitative parameters with a single analysis. This is achieved through transient pyrolysis of the samples up to 650 °C followed by combustion up to 850 °C, with hydrocarbons, CO and CO₂ measured during the thermal decomposition of both OM and carbonate minerals.

Carbonate minerals with low thermal cracking temperatures, such as siderite (<400 °C), can induce significant matrix effects which bias the TOC, MinC and OI Rock-Eval parameters. Here we assess the applicability of End-Member Analysis (EMA) as a means of correcting Rock-Eval thermograms for siderite matrix effects. For this, we performed Rock-Eval pyrolysis on sideritic sediments of Lake Towuti (Indonesia). New thermal boundaries were constrained in Rock-Eval thermograms using EMA to limit siderite matrix effects and improve TOC, MinC and OI calculations. Our approach allowed us to: (1) evaluate the influence of siderite matrix effects on Rock-Eval thermograms; (2) properly exploit a Rock-Eval dataset to characterize the type and sources of OM in siderite-rich sediments and (3) identify the OM behind degradation and mineralization processes. The Rock-Eval dataset revealed sediments with a substantial amount of refractory OM, especially in those where TOC is high and HI characteristic of autochthonous biomass. These results, associated to alternative indices used to assess OM preservation, suggest that refractory OM is residually enriched following strong degradation of labile compounds. Finally, relatively labile and refractory organic fractions may be consumed in the formation of siderite during this sequential process of OM mineralization.

1. Introduction

Sedimentary organic matter (OM) in marine and lacustrine sedimentary records is widely used as an indicator of changes in past depositional environments. Changes in OM quality and amounts can indicate the sources (aquatic/terrestrial) of sedimentary OM, the paleoecology (e.g., productivity) of aquatic systems, and help to identify the external drivers (climate, anthropogenic) leading
to these changes (Dean et al., 1997; Meyers, 1997; Meyers and Lallier-Vergès, 1999; Aritzegui et al., 2001). Fresh OM can be easily degraded by oxidation, respiration and anoxic microbially-mediated decomposition in the water column and within the sediment. The most labile organic fraction, such as microbial biomass or water-soluble OM, will be mineralized into CO₂ and CH₄, and contribute to the precipitation of other mineral phases, such as carbonates (Henrichs, 1993), potentially leaving behind the most recalcitrant OM. A better understanding of the underlying processes that convert total organic carbon (TOC – in wt%) to mineral carbon (MinC – in wt%) is therefore crucial for accurate reconstructions of depositional and post-depositional environments.

Thermal analyses are especially useful since specific temperature thresholds enable the distinction between TOC and MinC. Among the most common techniques, Rock-Eval pyrolysis (Espitalié et al., 1985) provides measurements of both TOC and MinC, as well as indices that can be used towards disentangling OM sourcing: the Oxygen Index (OI) and Hydrogen Index (HI), or the g CO₂ and g HC per g of TOC, respectively. These indices have widely been used to discriminate between sources of OM in previous studies (e.g., Tyson, 1993; Meyers, 1997; Meyers and Lallier-Vergès, 1999) and enabled, for example, the reconstruction of variations in authigenic biomass as a result of climate change (Aritzegui et al., 2001; Steinmann et al., 2003) and erosional patterns in subalpine sediments due to anthropogenic impact (Giguet-Covex et al., 2011; Bajard et al., 2017).

To achieve these results, the Rock-Eval analyser (Vinci, France) performs a pyrolysis of the samples to 650 °C, followed by combustion to 850 °C, with hydrocarbons, CO and CO₂ measured during the thermal decomposition of OM and carbonate minerals. The main advantage of the Rock-Eval method lies in the simple and fast analysis by means of quantifying CO and CO₂ released during the analysis (Dean et al., 1997; Meyers, 1997; Meyers and Lallier-Vergès, 1999) and enabled, for example, the reconstruction of variations in authigenic biomass as a result of climate change (Aritzegui et al., 2001; Steinmann et al., 2003) and erosional patterns in subalpine sediments due to anthropogenic impact (Giguet-Covex et al., 2011; Bajard et al., 2017).

This prevents the accurate measurement of MinC and TOC, while also leading to over- and underestimations of the OI and HI indices respectively. Previous studies (Pillot et al., 2014; Milesi et al., 2016; Sebag et al., 2018) have shown that siderite matrix effects can be corrected when processing Rock-Eval thermograms (evolved gas versus temperature). Milesi et al. (2016) suggested a siderite-matrix effect correction derived from Rock-Eval for Paleozoic sediments, which assumes that OM has a constant CO/CO₂ ratio with the excess CO₂ originating from siderite. However, siderite also releases variable amounts of CO during pyrolysis, with the result that the CO/CO₂ ratio cannot be satisfactorily assumed. A more recent study proposed a correction protocol based on thermogram analysis by means of quantifying CO and CO₂ released during the thermal decomposition of siderite in Holocene tropical lake sediments (Sebag et al., 2018). Nevertheless, the deposits which Sebag et al. (2018) analyzed were homogeneous in lithology and characterized by low MinC (0.2–1.9%). Thus, an alternative approach needs to be developed for more complex lithologies, with variations in the nature and quantity of carbon fractions to evaluate the applicability of the Rock-Eval correction method.

The Towuti Drilling Project (TDP), carried out through the International Continental Scientific Drilling Program (ICDP), aims to understand the climatic, biological, and geomicrobiological evolution of Lake Towuti, a part of the Malili lakes system in Indonesia, during the Pleistocene (Russell et al., 2016). Here, we used Rock-Eval analysis to study sediments acquired by the TDP, which have variable lithologies and abundant siderite (Russell et al., 2016). Rock-Eval data show different OM characteristics in samples where MinC values (>0.3–0.5%) indicate the presence of carbonates inducing potential matrix effects. Therefore, we used a novel End MEMBER Analysis (EAMA) approach to deconvolve Rock-Eval thermograms and defined accurate thermal boundaries for organic and inorganic carbon. Following this step, we estimated siderite abundance and calculated matrix effect-free Rock-Eval parameters. Finally, we utilized our dataset for qualitative OM characterization, i.e. determination of sources and identification of degradation processes preceding the formation of siderite.

2. Local setting, sampling and lithology

2.1. Study Site

Lake Towuti (2.75°S, 121.5°E, 318 m a.s.l.) is a tectonic lake located in central Sulawesi, Indonesia (Fig. 1). With a surface area of ~560 km² and a maximum water depth of 203 m, it is the largest of a set of five basins forming the Malili lake system. Lying within the East Sulawesi Ophiolite complex, Lake Towuti has a catchment of ~1500 km². The tropical and humid climate conditions, with precipitation averaging 2700 mm yr⁻¹ (Konecky et al., 2016), leads to erosion and extensive lateritic soil formation (Morlock et al., 2018). Most of the lake is surrounded by a dense rainforest. However, a recent increase in agricultural activity, particularly in the northern part of the catchment, has led to substantial deforestation (Vullemen et al., 2017; Morlock et al., 2018). Water chemistry is dominated by Mg²⁺ and HCO₃⁻ and low sulfate concentrations (1.5–2 ppm) with circumneutral pH (7.3–7.8). Nutrient concentrations are close to, or below, the detection limit. Lake Towuti one of the least productive lakes on Earth (Lehmsluoto et al., 1997; Haffner et al., 2001). The water column is weakly thermally stratified, with anoxic conditions below 130 m, allowing for an enrichment of dissolved Fe⁴⁺ (0.12 ppm) (Costa et al., 2015; Vullemen et al., 2016). OM in modern sediments seems to be mainly sourced from authigenic production as shown by a C/N ratio averaging 10.8 (Meyers and Lallier-Vergès, 1999; Hasberg et al., 2018). Higher ratios, located in front of the main inlets and steep slopes, support fluvial OM supply from terrestrial sources in near shore areas.

2.2. Lithology and sampling

Our samples (n = 166) are derived from a drill core composite stratigraphic section of the upper 113 m of site TDP-TOW15-1 (Fig. 1), including holes 1A, 1B, 1D, and 1F. The upper ~100 m of sediments in this section were continuously deposited in a lacustrine environment and likely represent hundreds of thousands of years of lake history (Russell et al., 2016). Sediments below 100 m indicate deposition in shallow lacustrine, riverine, and swamp environments (Russell et al., 2016).

Lake Towuti's sediments principally consist of an alternation of two types of unconsolidated clays: green clays and red clays, the latter of which contain variable concentrations of siderite (Russell et al., 2014, 2016; Vogel et al., 2015). Mineralogical analyses of surficial sediments and shallow cores show that fine-grained sediments are primarily composed of phyllosilicates, namely serpentine, smectite and kaolinite, with variable but generally low, amounts of silt-sized silicilastics and diverse occurrence of Fe-
phases such as siderite, magnetite and Fe$^{3+}$-oxides (Tamuntuan et al., 2015; Vogel et al., 2015; Goudge et al., 2017; Hasberg et al., 2018; Morlock et al., 2018). Fine-grained pelagic sediments in the core are occasionally interspersed with coarser grained turbidites and concretionary levels rich in siderite (Russell et al., 2016). Despite the low primary productivity today, OM can be abundant in larger quantities, such as the few diatomaceous lithologies, which have been observed at depth in the cores (Russell et al., 2016).

3. Methods

3.1. The Rock-Eval method

All samples were freeze-dried and homogenized using a mortar and pestle. Rock-Eval analyses were performed with a Rock-Eval 6 pyrolyser (Vinci Technologies) at the Institute of Earth Sciences of the University of Lausanne (Switzerland). Between 55 and 70 mg of freeze-dried and powdered sample material were placed in Incoloy crucibles for analyses. The Rock-Eval analytical process consists of two sequential heating steps under different ambient conditions (Espitalié et al., 1985; Lafargue et al., 1998; Behar et al., 2001) while recording the different volatile fractions of the OM as a function of the increasing temperature. The first step is pyrolysis under an inert atmosphere ($N_2$). Free hydrocarbons (HC) are first released isothermally at $200^\circ C$ for 3 min and measured as signal $S1$ (expressed in mg HC g$^{-1}$ sediment) by a flame ionization detector (FID). Samples are then progressively heated up to $650^\circ C$ at a rate of $25^\circ C$ min$^{-1}$. Long-chained C-compounds and kerogen, crack and release HC, which is recorded as the $S2$ fraction (mg HC g$^{-1}$ sediment, Fig. 2A). Hydrocarbons released during these steps are measured by a flame ionization detector (FID), and the abundance of hydrocarbons measured as a function of time is called a thermogram. Simultaneously, the cracking of kerogen and OM also releases carbon dioxide ($CO_2$) and carbon monoxide ($CO$) which are measured by an infrared-cell (IR). Carbon oxides’ thermograms are expressed in mg $CO_2$ and mg $CO$ per g of sediment, respectively (Fig. 2), and are referred to as $S3$ and $S3CO$. Using the $S1$, $S2$, $S3$ and $S3CO$ thermograms, the pyrolysed carbon ($PC$, wt%), or the fraction of TOC which is proportional to the amount of hydrogen and oxygen in the OM, is measured. The second step in the Rock-Eval method is a combustion under oxidative conditions ($N_2/O_2$: 80/20). Following a short cooling step, samples are progressively reheated from 300 up to $850^\circ C$. The combusted CO is recorded as the $S4CO$ thermogram and $CO_2$ as $S4CO_2$ and $S5$. Both oxides are measured (by IR) to quantify the residual fraction of the TOC,

Fig. 1. Modified after Russell et al. (2014). Location of Lake Towuti within the Malili Lakes system, Sulawesi, Indonesia. The drilling site, TDP Site 1, is indicated by the red star. (For interpretation of the references to colour in this figure legend, the reader is referred to the web version of this article.)
compounds of vascular plants (Meyers, 1997; Carrie et al., 2012), and other OM rich in long-chained carbon polymers, such as organic compounds of vascular plants (Meyers, 1997; Carrie et al., 2012), oxygen to be combusted and volatilized. Low PC/RC ratios are typically of OM, referred to as residual carbon (RC – wt%), which requires external oxygen to be combusted and volatilized. Low PC/RC ratios are typical of OM rich in long-chained carbon polymers, such as organic compounds of vascular plants (Meyers, 1997; Carrie et al., 2012), or residual/degraded OM (Henrichs, 1993). While the measured HC is exclusively of organic origin, carbonates also contribute to the production of CO₂ and CO within the S₃ fraction, with different cracking temperatures depending on their composition (Pilot et al., 2014).

Standard Rock-Eval parameters (TOC; MinC; HI; OI) and the OIRₑ₆ (a variety of OI, calculated in mg O₂ g⁻¹ TOC) were calculated from thermograms using the areas between boundary temperatures based on the empirically determined equations of Lafargue et al. (1998; Table 1). The thermal boundary between organic and mineral carbon in CO₂ thermograms from the first step is set at 400 °C (Lafargue et al., 1998), below which CO₂ is considered to be of organic origin (S₃, Fig. 2B). Above 400 °C, CO₂ is considered to have a mineral origin (S₃', Fig. 2B). Conversely, the thermal boundary in CO thermograms is variable and defined where a minimum of CO-intensity is observed (400–600 °C). If no minimum could be measured, 550 °C is taken as a default value (Fig. 2C). At lower temperatures CO intensities are considered exclusively organic (signal S₃CO, Fig. 2C). As temperature increases, CO additionally evolves from the reaction of CO₂ with residual organic carbon, following the Boudouard equilibrium reaction (CO₂ + C ↔ 2CO; Lafargue et al., 1998). At high temperatures it is assumed that the CO is involved in the reaction is predominantly originating from carbonates. Therefore, above the defined minimum, CO is considered to evolve from a mixture of organic and inorganic sources (signal S₃'CO, Fig. 2C).

The presence of siderite exerts a significant complication as it overlaps with the commonly used Rock-Eval thermal boundaries. This is because siderite starts to thermally decompose below 400 °C, well within the range of the cracking of OM. This challenges the use of standard Rock-Eval parameters because siderite-MinC can contribute to intensities used for the calculation of TOC and OIRₑ₆, as well as parameters that are normalized against TOC such as the HI. However, detecting and correcting siderite effects is possible. It can be differentiated from other carbonates because it simultaneously produces both CO and CO₂ at relatively low temperatures due to the additional reaction of CO₂ with Fe²⁺-oxides (FeCO₃ → FeO + CO₂; 3FeO + CO₂ → Fe₂O₃ + CO). Consequently, thermograms from siderite-rich samples will show twin features on CO₂ and CO thermograms (Fig. 3, simultaneous CO₂ and CO peaks), whereas other carbonates will not (Espitalié et al., 1980).

Fig. 2. Standard Rock-Eval temperature ranges for HC (A), CO₂ (B) and CO (C) thermograms in Lake Towuti sediments, modified after Behar et al. (2001). The illustration explains how intensities are conventionally split into organic and mineral carbon integrals.

</table>
of pyrolysed HC, are normalized to 100% and divided into 5 temperature ranges, from the most thermally labile to the most thermally refractory organic fraction (A1: 280–340 °C, A2: 341–400 °C, A3: 401–460 °C, A4: 461–550 °C, A5: 551–650 °C). The I-index (I = log [(A1 + A2)/A3]) is commonly used to assess the contribution of the most thermally labile fraction to the sedimentary OM and may be used to estimate the degree of OM preservation. Albrecht et al. (2014), showed that the I-index is sensitive to degradation of biological tissues into soil and sedimentary OM. Conversely, the R-index (R = (A3 + A4 + A5)/100) provides a qualitative measure of the thermal stability of bulk OM and can therefore be used to estimate the degree of OM degradation. Together, these indices can be used as indicators for OM degradation and mineralization. Indeed, by default, both indices are strongly inversely correlated when thermal stability is driven by preferential mineralization of the labile fraction; i.e. when the refractory fraction increases at the expense of the labile fraction during the degradation of OM.

3.2. X-ray diffraction and elemental CHNS analysis

To confirm the presence or absence of siderite in samples with high and low MinC values, we performed X-ray diffraction (XRD) analyses on freeze-dried and powdered bulk sediment samples, with detection limits fluctuating between 0.2 and 0.5 wt% of MinC (Table S1 – supplementary material – Fig. A1). Whole sediment compositions were determined using a Thermo Scientific ARL X-TRA diffractometer at the Institute of Earth Sciences (University of Lausanne, Switzerland), following the methods described by Adatte et al. (1996). Reported intensities of siderite were observed at 2θ = 32°.

Additionally, total carbon (TC) and TOC, were measured on 6 samples, covering the range of TOC and MinC values inferred by Rock-Eval analyses (Table S1, Figs. A2 and A3), with a Carlo Erba EA 1108 Elemental Analyser at the Institute of Geological Sciences, University of Bern, to evaluate the Rock-Eval dataset before and after EMA. Inorganic carbon was removed using 1 M HCl at 70 °C prior to TOC content determination. Total inorganic carbon (TIC) was calculated as the difference between TC and TOC.

3.3. End-Member Analysis

Thermal boundaries used in the equations for the determination of Rock-Eval parameters (Lafargue et al., 1998) were empirically defined considering the cracking temperature ranges of organic and inorganic carbon phases. The accuracy of the empirically determined thermal boundaries was tested in this study using End-Member Analysis (EMA). In particular, EMA was applied to better constrain the contribution of siderite C to quantify the MinC.

We used AnalySize, a Matlab-based Graphic User Interface typically used for processing and unmixing of grain-size distribution data (Paterson and Heslop, 2015). We followed a Single-Specimen Unmixing (SSU) method, which unmixes individual grain-size distributions (GSD) into unimodal parametric distributions using a least squares approach. Applications of EMA on GSD are commonly used to characterize sediment transport processes. Thermograms are in many ways similar to grain-size distribution spectra. This is because they consist of overlapping peaks resulting from OM and mineral carbon phases cracking at variable temperature ranges. Likewise to its application on GSD, EMA on Rock-Eval thermograms may facilitate unmixing of the thermograms into carbon endmembers and help to qualitatively characterize carbon composition in sediments.

There are two main constraints with SSU. The statistical approach presumes that intensities can be described as a linear mixture of the end-member components in which the abundances.
of each end-member must be nonnegative and sum to one (100%) (Paterson and Heslop, 2015). CO and CO$_2$ intensities in thermograms are already nonnegative values. To allow our dataset to sum to one, thermograms were normalized to 100%, i.e. intensities at each temperature increment ($^\circ$C) of each thermogram were divided by the integral of the entire signal (200–650 $^\circ$C).

The parametric EMA was applied to CO and CO$_2$ thermograms using a lognormal distribution fit. Thermograms measured at the oxidation step (S4CO, S4CO$_2$, S5; Table 1) were not considered for EMA since all siderite should have been degraded during the pyrolysis stage (Espitalié et al., 1985). This is clearly visible in thermograms (Fig. 3) with siderite intensities negligible after 550 $^\circ$C.

Each end-member’s intensity was integrated and included in the equations of Rock-Eval parameters (Behar et al., 2001). Results of EMA and in particular the resulting relative amounts of siderite in our samples, were compared to the parameters obtained via the Rock-Eval classic thermal boundaries.

4. Results

4.1. Uncorrected standard Rock-Eval parameters

TOC ranges between 0.18 and 6.05 wt% (Table S2, supplementary material), which is within the range of modern surface sediments (0.17 and 6.43 wt%; Hasberg et al., 2018). RC (residual carbon) values are generally higher than PC (pyrolysed carbon), barely reaching PC/RC ratios > 1. Only 18 out of the 166 samples have a PC/RC > 1. MinC ranges between 0.11 and 4.65 wt%.

HI (15–300 mg HC g$^{-1}$ TOC) is positively related to the TOC content. OI and OI$_{REE}$ are very high, reaching values above 1000 mg CO$_2$ and mg O$_2$ g$^{-1}$ TOC, respectively, especially where TOC contents are below 2 wt% (Table S2). Such high values are comparable to those reported (up to 1500 mg O$_2$ g$^{-1}$ TOC) from Gabonese lake sediments with a relatively high contribution of sand and charcoal (Sebag et al., 2013). The I index, an estimate of the preservation of the labile OM, ranges between –0.61 and 0.56. Conversely, the R index, representing the relative abundance of the thermally stable (refractory) OM, ranges between 0.50 and 0.89 (Table S2).

4.2. Siderite content and matrix effect

XRD measurements confirmed macro- and microscopic observations of the presence and absence of siderite. Siderite was systematically detected by XRD in samples with variable MinC (0.5–3 wt%, Fig. 4). However, siderite was only occasionally detected at MinC values < 0.5 wt% (i.e. 0.3 wt%, Fig. 4). Although XRD cannot provide precise estimates of siderite content, the comparison of XRD peak intensities with the Rock-Eval MinC shows very good agreement ($R^2 = 0.91$, Table S1) and both values are positively correlated. Moreover, other carbonate minerals were not detected by XRD. It can therefore be assumed that MinC originates from siderite while other carbonate phases are either absent or below the detection limit of XRD. This is in good agreement with previous combustion tests (Pillot et al., 2014), which show that the amount of siderite is proportional to the signal of CO$_2$ and CO thermograms, used in the calculation of MinC.

As revealed by previous studies (Espitalié et al., 1985; Sebag et al., 2018), siderite can contribute to the S3 and S3CO integrals (used to calculate the PC and TOC; Table 1). This affects Rock-Eval TOC and MinC assessment and can strongly bias the calculation of OI and OI$_{REE}$ values which are particularly sensitive to these matrix effects on S3 and S3CO thermograms. Lake Towuti sediments with low TOC and high siderite content are particularly prone to these siderite-induced matrix effects and therefore require an evaluation and eventually a correction prior to calculating Rock-Eval parameters. To determine objectively whether siderite is accountable for the assumed matrix effects, we followed an approach totally independent of the lithological facies and focused only on our Rock-Eval thermograms. Thus, we divided the entire dataset into two groups using the median (0.31 wt%) of MinC: high MinC (siderite-rich samples) and low MinC (siderite-poor samples). This was done under the assumption that in Lake Towuti sediments MinC calculated from uncorrected Rock-Eval thermograms indicates the presence of siderite as suggested by the correlation of MinC with the XRD intensity peaks at 32.1 $^\circ$ (Fig. 4). The CO$_2$ and CO thermograms of the high MinC group show high intensities between 350 and 550 $^\circ$C, whereas intensities in this temperature range are low in the low MinC sample set (Fig. 3). These observations are also consistent with Pillot et al. (2014) and Sebag et al. (2018) who demonstrated strong correlation between siderite content and intensity at these temperature ranges in Rock-Eval thermograms.

Based on the grouping assigned to the Lake Towuti sample set, oxygen indexes (OI and OI$_{REE}$) and TOC, two parameters sensitive to siderite effects on S3 and S3CO integrals also reveal two distinct populations related to siderite abundance (Fig. 5A and B). While both parameters present an outstanding correlation in the low MinC group, those of the high MinC spread out, particularly in

![Fig. 4. X-ray diffractograms of samples from the High MinC (MinC > 0.3%) and Low MinC (MinC < 0.3%) groups showing the presence or absence of the characteristic siderite diffraction at 2θ = 32°.](image-url)
samples with TOC < 2 wt%. This suggests possible matrix effects on OI, OI RE6 and TOC.

4.3. Carbon distribution by End-Member Analysis

We tested different parametric distributions and optimized the linear independence of the end members (EM) by choosing the lowest maximum squared linear correlation factors ($R^2$) between the different fitted EM. Indeed, a low linear correlation between end members is convenient since high EM correlation is an indication of overfitting where one end member is a near duplicate of another (Paterson and Heslop, 2015).

A lognormal parametric distribution in CO$_2$ thermograms with 6 EM accounted for a specimen median $R^2$ value of 98.6% and a maximum EM linear correlation of $R^2 = 0.07$. The same parametric distribution in CO thermograms with 5 EM accounted for a specimen median $R^2$ value of 95.8% with a maximum EM linear correlation of $R^2 = 0.20$.

Using alternative parametric distributions and/or forcing the analysis to fewer or more EM, did not improve the EM linear correlation factors.

Considering a temperature of 380–560 °C for siderite and the temperature peaks given by the algorithm, two EM in the CO and three EM in the CO$_2$ thermograms were assigned to inorganic carbon (Fig. 6A). Deconvolution of the siderite signal of CO and CO$_2$ thermograms into 2 (at 444 °C and 473 °C) and 3 (at 419 °C, 450 °C and 479 °C) peaks respectively, could be the result of a thermal shift–matrix effect caused by carbonate mass variations, different degrees of crystallinity, or other mineral matrix effects (Espitalié et al., 1980; Marchand et al., 2008; Pillot et al., 2014; Kang et al., 2015).

Pillot et al. (2014) combusted rocks containing different degrees (5–40 mg) of pure siderite under oxidative conditions and suggested mass variations as having a small effect in the temperature at which they release their maximum of CO$_2$ (515–519 °C). However, the content of siderite in Lake Towuti sediments seems to influence considerably its peak of cracking temperature. Indeed, samples with MinC values > 1 wt% show that CO$_2$ intensity peaks with a mineral origin evolve in temperature with varying MinC at a rate of ca. 12 °C per 1 wt% of MinC ($R^2 = 0.7$; Table S3). Considering the mass range of the samples (55–70 mg) and the molar mass of siderite (115.8 g mol$^{-1}$) this corresponds to rates between 1.8 and 2.3 °C g$^{-1}$ of siderite, respectively.

The temperature peaks at which siderite decomposes in our samples are considerably lower than those found by Pillot et al. (2014) who combusted the carbonates (i.e. under oxidative conditions). Marchand et al. (2008) tested the decomposition of pure siderite and rhodochrosite under pyrolysis conditions and obtained results similar to those of Pillot et al. (2014) suggesting, hence, that oxidative conditions will not particularly shift the peak at which carbonates decompose. It is likely that crystal size neither has a substantial impact on the temperature at which carbonates decompose. Indeed, it has been demonstrated (Pillot et al., 2014) that different crystal sizes of pure calcite (chalk and marble) changed the temperature of maximal release of CO$_2$ by only 2–4 °C.

Conversely, other mineral matrix-effects might considerably impact the cracking of carbonates. Experimental thermal decomposition of pure siderite (Marchand et al., 2008) or siderite within a rock matrix (Pillot et al., 2014) occurs above 510 °C. Carbonates within a clayey matrix decompose at a lower range, between 400 and 475 °C (Marchand et al., 2008; Sebag et al., 2018; this study). Moreover, the presence of Fe-oxides might reduce the thermal stability of siderite by more than 100 °C (Kang et al., 2015). Sediments in Lake Towuti and many other tropical environments (Sebag et al., 2018) contain abundant Fe-oxides thus making a shift towards lower siderite decomposition temperatures more likely. Addition-

Fig. 5. High MinC (siderite-rich) and Low MinC (siderite-poor) samples reveal different TOC vs. OI$_{RES}$ (A) and TOC vs. OI (B) properties. (C) With End-Member Analysis (EMA), the trend defined by TOC vs OI$_{RES}$ is tight-clustered whether samples contain high or low/no siderite. (D) Scatterplot of TOC vs. OI presents tight clustering in lakes with low/no siderite (Lake Geneva, Gascón Díez et al., 2017; Lake Brêt, Thevenon et al., 2013). MinC in these systems is principally composed of calcite. Note the different scales in the different panels.
Fig. 6. Results of the End Member Analysis (EMA) performed on thermograms to identify and quantify carbon phases. (A) End-Members (EM) density obtained by EMA in CO and CO2 thermograms. Three and two EM, respectively, were assigned to siderite. Three End-members were attributed to organic phases. Dashed lines indicate the relative average intensity of thermograms. (B) EM were identified as siderite (Corg-refractory), labile Corg (Corg-labile), refractory Corg (Corg-refractory), and an intermediate Corg phase moderately refractory (Corg-intermediate). Integrated intensities were included in the equations of Rock-Eval parameters (Behar et al., 2001) such as MinC and TOC. (C) Corg-labile and Corg-refractory are both negatively correlated to the MinC calculated by EMA (EMA-MinC) suggesting consumption of both Corg phases. However, Corg-labile is generally more abundant than Corg-refractory, even at high MinC, indicating resilience of Corg-labile to mineralization processes.

ally, SEM-EDX analyses of siderite in Lake Towuti sediments show substitution of Fe by Mn with an average Mn atomic/Fe atomic of 0.13 (Vuillemin et al., 2019). Since rhodochrosite decomposes at higher temperatures (Marchand et al., 2008; Pillot et al., 2014), its presence could also explain some of the variability of the cracking temperature of siderite.

The three remaining EM in CO (peaks at 331 °C, 453 °C and 644 °C) and CO2 (peaks at 317 °C, 453 °C and 646 °C) thermograms were assigned to organic carbon. Considering the different temperature peaks of the EMs and the thermal properties of OM, we indexed them as labile organic carbon (Corg-labile), resistant organic carbon (Corg-resistant), and refractory organic carbon (Corg-refractory) (Fig. 6A). Intensities of EM attributed to siderite were combined and indexed as inorganic carbon (Cinorg). In light of the EMA results, the Corg-resistant appears to be a substantial source of CO and CO2 in pyrolysis (Fig. 6B). However, CO and CO2 in some sediments are almost exclusively derived from carbonates.

EMA-derived organic and inorganic carbon in CO and CO2 thermograms were used to calculate TOC (EMA-TOC), MinC (EMA-MinC), and Rock-Eval indices (EMA-HI and EMA-OIRES). Briefly, the total intensity of CO and CO2 thermograms was proportionally redistributed into organic and inorganic moieties based on the discriminatory EM’s (CorglCO2 and CinorglCO2; CorgCO and CinorgCO), replacing classic CO2 and CO signals (S3 and S3; S3CO and S3CO). EM based values were then included in the standard formulas (Table 1) to calculate Rock-Eval parameters.

The Boudouard effect, assuming CO above 550 °C as half organic and half mineral (Fig. 2), was not considered in calculations because (1) siderite is thought to be entirely consumed above 550 °C; (2) the effect is negligible below 550 °C (Espitalié et al., 1985); and (3) other carbonates are absent. Therefore, all CO from Corg-refractory peaks is assumed as exclusively organic.

4.4. Rock-Eval thermal boundaries by End-Member Analysis

Parameters obtained using EMA are in agreement (Table S1) with those obtained with classic Rock-Eval thermal boundaries although there are slight differences in the TOC and MinC distribution between both approaches. EMA-TOC concentrations (0.70–6.22 wt%) increased by up to 0.39 wt% at the expense of the EMA-MinC (0.01–4.26 wt%), suggesting an overestimation of the initial MinC. This overestimation is almost exclusive to samples with MinC < 1 wt%. Samples with MinC > 1 wt% are usually underestimated. Additionally, using EMA allowed constraint of MinC values of zero. This is consistent with lithological observations in most of the green clays, where siderite is absent. EMA-OI values range from 109 to 2392 mg CO2 g–1 TOC and EMA-OIRES values are comprised between 110 and 1872 mg O2 g–1 TOC, much higher than values obtained using conventional Rock-Eval thermal boundaries.

In any case, both approaches produce OI and OIRES values that are exceptionally high and exceed by far those of previously reported values (up to ~500 mg CO2 g–1 TOC) in studies carried out in diverse environments (Meyers and Lallier-Vergès, 1999; Li et al., 2000; Steinmann et al., 2003; Vannière et al., 2008; Debret et al., 2014; Omodeo-Salé et al., 2016). These studies have similar and coherent OI values, suggesting a specific type of OM even though their settings are different. Conversely, very high OIRES Values (up to 1500 mg O2 g–1 TOC) have been reported (Sebag et al., 2013; Mahicka Obame et al., 2014) in tropical environments and thus possibly indicate highly degraded OM. OIRES values higher than 1000 mg O2 g–1 TOC have as well been reported in C horizons from cambisols in mountain areas where OM is scarce and strongly degraded (Gigué-Covex et al., 2011; Bajard et al., 2017). Despite the high values, EMA-OIRES correlate very well with EMA-TOC (Fig. 5C) and the High and Low MinC constitute this time a more tightly clustered single group as is the case in samples with low or no siderite from one Alpine (Lake Geneva; Gascón Díez et al., 2017) and one artificial lake in Switzerland (Lake Brêt; Thevenon et al., 2013; Fig. 5D). This suggests that EMA-derived Rock-Eval parameters are widely unbiased by siderite matrix effects.

5. Discussion

5.1. End-Member Analysis for siderite matrix effect-free Rock-Eval parameters

TOC, MinC, and Rock-Eval indices for OM characterization calculated from uncorrected Rock-Eval thermograms are clearly affected by siderite matrix effects in Lake Towuti sediments. Our approach corrects these Rock-Eval matrix induced biases, improves estimates of OM content in sediments, and optimizes indices used
for OM characterization. Here we used the TOC vs. O_{LR} scatterplot as a matrix effect proxy. Samples with low or no siderite have an exponential relationship with tight clustering (Low MinC, Fig. 5A) as previously shown in other lacustrine environments containing low or no siderite (Fig. 5D; Thevenon et al., 2013; Gascon Díez et al., 2017). Samples with an excess or deficiency in CO_{2} with a siderite origin spread out in a much looser clustering (High MinC; Fig. 5A) as for Lake Towuti sediments containing siderite. The improvements from our EMA correction on TOC and O_{LR} values are clearly demonstrated in Fig. 5C, where the relation of TOC with O_{LR} for High and Low MinC samples is similar after correction.

In Lake Towuti, siderite matrix effects only affect TOC moderately—since most of the TOC (76% for Low MinC and 72% High MinC) is composed of RC, which is not affected by matrix effects because it is measured during the oxidation step. This emphasizes that the co-pyrolysis of siderite and most of the OM is limited and that the overlap of signals is low. Conversely, some PC values, the fraction of TOC (24% for Low MinC and 28% High MinC) measured during the pyrolysis step, were corrected for matrix effects and increased at the expense of MinC, after EMA. The underestimation of PC values can be explained by the limit set at 400°C by the conventional approach to split the organic and inorganic carbon pools (Fig. 2), despite the refractory OM pyrolysing above that limit (Fig. 6) and even beyond 550°C, as shown in our thermograms (Fig. 3). This is why MinC is overestimated when its values are lower than 1 wt%. Conversely, if siderite is abundant (MinC > 1 wt%), intensities below 400°C are high enough to trigger a bias, and as a result MinC is underestimated. Moreover, EMA showed an abundant C_{org-resistant} component (32% of total CO_{2} and 35% of total CO) in Lake Towuti sediments, potentially combusting along with siderite (Fig. 6). However, siderite-rich sediments in this study contain low TOC, and hence also low total C_{org-resistant}. Therefore, the bias is generally modest and specific to a few samples with high PC and abundant siderite. For instance, after EMA, samples with EMA-PC and EMA-MinC values > 1 wt% showed a carbon redistribution between 0.26 and 0.39 wt% (Table S2), much larger than the average correction (0.14 wt%).

The EMA routine allowed us to evaluate and better constrain TOC and MinC in samples with variable amounts of organic carbon and siderite compared to other Rock-Eval siderite-matrix effect corrections (Milesi et al., 2016; Sebag et al., 2018). Samples with low PC and abundant siderite, as is the case for the majority, present low to moderate matrix effects. However, EMA appears particularly valuable in settings where PC and MinC values are high. Moreover, our novel approach allowed us to satisfactorily estimate siderite content in Lake Towuti sediments. Based on EMA-MinC, modal concentrations of siderite in the bulk sediment range from 0 to 45 wt%, with an average of 7 wt%, which is consistent with macro- and microscopic observations. Conversely, the already high O_{LR} values considerably increased after correction. Similar increases in O_{LR} after correcting carbonate matrix effects have been reported in other studies; indeed, this is expected as the correction removes carbon from estimates of TOC. For instance, Baudin et al. (2015) performed Rock-Eval analyses in Timor Sea sediments and showed simultaneous CO_{2} production from residual carbon (RC) and poorly crystallized calcite. In that study, after correction of TOC values (0.81 wt% ± 0.04), OI increased to values as high as 750 mg CO_{2} g^{-1} TOC. Likewise, in this study, EMA showed that a small fraction of C_{org-resistant} was erroneously accounted as C_{inorg} and TOC correction resulted in an increase of O_{LR} values. Therefore, low TOC content and particularly low PC values are sufficient to generate extremely high OI values, especially in Towuti sediments which are already enriched in refractory oxygenated OM. This phenomenon was previously described as a decrease in the signal-to-noise ratio with decreasing TOC (Katz, 1983; Peters, 1986; Espitalié et al., 1985) generating a low TOC-matrix effect.

Finally, to validate Rock-Eval parameters, we measured TOC and TIC in selected samples with an Elemental Analyser (EA) and siderite intensities by XRD (c.f. section 4.2). Although MinC and TOC, before EMA, correlate very well with TIC and TOC measured by EA respectively (Table S1), the slope of the linear regression deviates from the 1:1 line (e.g., MinC = 1.23 TIC + 0.09, R^{2} = 0.97), suggesting systematic offsets between the two methods. Differences in Rock-Eval carbon distribution (organic versus inorganic) before and after EMA are relatively small—but still relevant considering the low OM content of some Lake Towuti lithologies. However, corrections are not large enough to have an impact on the correlation factors and the slope of Rock-Eval parameters versus those obtained by the Elemental Analyser and XRD (Table S1, Figs. A1–A3). This points to methodological inconsistencies. For instance, the EA, requires prior acidification and separate measurements to constrain the inorganic carbon content. Acidification techniques are known to partially remove labile and soluble organic matter (Marchand et al., 2008; Levesque et al., 2009; Larson et al., 2010; Brodie et al., 2011) possibly leading to an underestimation of TOC values. Conversely, using weak acids can prevent the complete dissolution of carbonates, especially siderite, which is more resistant to acid dissolution than other carbonates (Larson et al., 2010; Brodie et al., 2011; Schlacher and Connolly, 2014). This could explain why C_{org} measurements of acidified samples are systematically lower than their equivalent TOC, obtained by pyrolysis. Although EMA could improve our Rock-Eval dataset, methodological inconsistencies are still obvious and require further investigation.

5.2. Sources of sedimentary organic matter in Lake Towuti

Carbonate matrix effect-free Rock-Eval parameters constitute a more reliable basis to characterize OM in lacustrine sediments. This is particularly true for HI and OI (and O_{LR}) indices which, plotted in the Pseudo van Krevelen diagram (Fig. 7), typify OM sources. Typically, OI and O_{LR} increase with OM rich in highly oxidized carbon chains whether they are transported from the catchment or formed by dehydrogenation and oxidation processes during early diagenesis (Jacob et al., 2004; Sebag et al., 2018). EMA-O_{LR} in this study (110–1872 mg O_{2} g^{-1} TOC) reach anomalously high values, most of them far beyond the usual range to characterize OM sources (Peters, 1986) in aquatic sediments (Meyers, 1997; Meyers and Lallicher-Vergès, 1999; Ariztegui et al., 2001; Steinmann et al., 2003; Baudin et al., 2015) and soils (Disnar et al., 2003). Some studies have reported high O_{LR} values from lignins (800 mg O_{2} g^{-1} TOC; Carrie et al., 2012), C horizons in cambisols (>1000 mg O_{2} g^{-1} TOC; Gigué-Covex et al., 2011; Bajard et al., 2017) and predominantly clastic lake sediments with abundant terrestrial OM in lateritic environments (>850 mg O_{2} g^{-1} TOC; Mabicka Obame et al., 2014; Sebag et al., 2018). However, high EMA-O_{LR} values could be likely the result of other matrix-effects, which in our case subsist the carbonates matrix-effect correction and affect the EMA-O_{LR} index. For instance, Fe-oxides may interact with OM (Grand et al., 2018) and clays may exert a thermal shielding effect (Espitalié et al., 1980) with, as consequence, an increase in the temperature at which OM cracks. Espitalié et al. (1985) empirically defined OI as reliable if TOC was >2 wt% and unreliable if <0.5 wt% because low TOC, causing high OI, complicates the conventional use of OI as an indicator of OM provenance. Half of our dataset presents EMA-TOC values >1.5 wt% and can, up to a certain point, be associated to highly oxidized carbon chains. However, O_{LR} values should be interpreted with caution and OM characterization in similar settings requires complementary analyses such as δ^{13}C and/or biomarkers.

Unlike O_{LR}, EMA-HI values are within the usual range of OM characterization and were unaffected by carbonate matrix-
effects. The entire dataset presents a relatively narrow range of EMA-HI (14–289 mg HC/g EMA-TOC), with low values consistent with allochthonous or highly oxidized OM and high values generally attributed to OM sourced from aquatic organisms (Tissot and Welte, 1984; Meyers and Lallier-Vergès, 1999). However, our EMA-HI values are still significantly lower than those of lipids characterizing algae (>500 mg HC g−1 TOC; Meyers and Lallier-Vergès, 1999; Carrie et al., 2012). Therefore, samples with moderate EMA-HI values support intermittent inputs of algal lacustrine OM to a terrestrial-like bulk OM that characterizes OM preserved in Lake Towuti sediments.

HI/OI ratios < 0.5, as it is largely the case for Towuti samples (Table S2), have been assigned to terrestrial/soil OM (Carrie et al., 2012; Sebag et al., 2018), and this is consistent with highly-degraded allochthonous OM originating from lateritic soils in the Lake Towuti catchment. Additionally, 87% of Lake Towuti sediments have EMA-PC/EMA-RC ratios < 1 (Table S2) and are equivalent to those of carbohydrates (cellulose, pectin) and fresh materials such as conifer needles or tree bark (Carrie et al., 2012). Although such indicators suggest OM in Lake Towuti as being primarily of terrestrial origin, long-chained carbon polymers can also originate from the accumulation of recalcitrant phases following oxidation and diagenetic degradation of the labile fraction (Henrichs, 1993; Jacob et al., 2004).

5.3. Depositional environments and early diagenesis in Lake Towuti

I and R indices can indicate the preservation and degradation state of organic matter and, unlike OIRES values, they are derived from S2 thermograms and thus unbiased by siderite and low TOC-matrix effects. In the I-R diagram (Fig. 7B), the whole dataset indicates a strong correlation between these two indices. Following Sebag et al. (2016), this correlation indicates that the thermal stability of sedimentary OM is controlled by degradation processes. Indeed, an OM mixture from different sources would generate poorly related I-R indices (Sebag et al., 2016). Towuti water temperatures ranging between 28 and 30 °C (Costa et al., 2015) likely enhance degradation, which is further facilitated by methanogenesis, the most important OM mineralization pathway (444 ± 172 mmol m−2 yr−1 of organic carbon) after burial in Towuti sediments (Friese et al., 2018; Vuillemin et al., 2018).

According to the I-R indices (Fig. 7B), degradation is more substantial in samples with high EMA-TOC. Additionally, the few samples with a clear dominant algal component (EMA-HI > 130 g HC g−1 EMA-TOC) present the lowest I-index for a given R-index, suggesting substantial loss of the most labile OM, and appear more degraded than samples with low EMA-TOC. This supports different rates of OM degradation, which are particularly high in sediments with abundant algal OM (Fig. 7B). Greater productivity can explain the highest values of EMA-TOC and, if the OM is of planktonic origin, it is preferentially degraded compared to the more resistant terrestrial OM (Tyson, 1995). Moreover, EMA-HI correlates positively with EMA-TOC (Fig. 7C). A decrease of EMA-HI along with EMA-TOC suggests a loss of the labile fraction following degradation. According to previous studies (Huc et al., 1990; Tyson, 1995), HI values level out when sediments attain optimal preservation conditions, usually at TOC values between 3 and 6 wt% for siliciclastic marine and lacustrine sediments. At that stage, HI can be used to determine eventually the nature of the original sources of lipidic material (Tyson et al., 1995). Since our HI values do not level out, optimal OM preservation conditions were not achieved in Lake Towuti sediments and our EMA-TOC versus EMA-HI indicates intense degradation of labile autochthonous OM.

Hence, buried OM in our high EMA-TOC samples is depleted in the labile and likely residually enriched in the more recalcitrant OM and thus shows a predominance of terrestrially sourced OM. This is in agreement with the moderately high EMA-OIRES values with a terrestrial-like signature. If extremely high EMA-OIRES are due to a low EMA-TOC-matrix effect, as seen in Section 5.1, moderately high EMA-OIRES from kerogens could be the result of
accumulation of refractory phases. However, differentiating kerosenes with a terrestrial origin from those formed by in-situ degradation in samples with low EMA-HI and moderately high EMA-OM requires further investigation and possibly a detailed organic geochemical approach.

Finally, unlike EMA-TOC, EMA-MinC do not define a clear relation with the I-R indices (Fig. 7D) and degradation processes seem not to be related to the abundance of siderite. This points to a substantial contribution of siderite forming post-burial and thus after the majority of the OM has already been degraded. Indeed, according to EMA, $C_{\text{org-labile}}$ and $C_{\text{org-refractory}}$ both decrease with increasing $C_{\text{inorg}}$, suggesting that “labile” and “refractory” fractions are indistinctly mineralized (Fig. 6C) into intermediate phases such as CH$_4$ and CO$_2$ (Fries et al., 2018) prior to siderite formation. This brings to light different degradation processes of OM followed by a subsequent (diagenetic) transition of organic carbon to siderite (Vuillemin et al., 2019).

6. Conclusion

Despite its many advantages, a potential problem with Rock-Eval analysis arises from the bias introduced by matrix effects that hamper the robust determination of OI RE6, MinC and TOC values. Samples with abundant siderite thus require a suitable matrix-correction approach to generate unbiased Rock-Eval parameters.

Using End-Member Analysis (EMA) we were able to correct Rock-Eval thermograms for siderite matrix effects allowing for a more accurate determination of widely used parameters for quantitative and qualitative organic matter characterization. Carbonate matrix effects slightly affected TOC and MinC values since the major component of the organic carbon was obtained during the oxidation step and thus was not synchronous with the pyrolysis of siderite. However, very low TOC contents, and probably the presence of clays and Fe-oxides, induced anomalously high OI RE6 values, which could not be exploited using classic Rock-Eval interpretation schemes and should be interpreted with caution.

Standard Rock-Eval indices obtained by EMA combined with alternative indices derived from S2 thermograms (I-R) can be used as valuable indicators for OM sourcing and degradation in geochemically exceptional Lake Towuti sediments. The I- and R-indices suggested different degradation processes: in combination with high EMA-HI-values, they indicated an intermittent algal input to the sediments, followed by intense loss of the labile organic fraction; associated to high EMA-TOC and moderately high EMA-OM values, they indicated strong degradation and substantial accumulation of terrestrial-like OM in the sediments. Moreover, a correlation of I-R indices with the MinC could not be determined, suggesting that the majority of OM degradation processes precede siderite formation.

In summary, our EMA-Rock-Eval approach improves identification of the sources and the intensity of degradation of OM in ferroginous and siderite bearing sediments. Due to the relatively low amount of sample preparation required and rapid analysis EMA Rock-Eval approaches are particularly useful for generating high-resolution datasets for OM sourcing and quality and for targeting specific sediment intervals out of long sediment succession for more time-consuming analyses.
