Two Fe-N-C catalysts comprising only atomically-dispersed FeN_x moieties were prepared, differing only in the fact that the second catalyst (Fe_{0.5}-NH₃) was obtained by subjecting the first one (Fe_{0.5}-Ar) to a short pyrolysis in ammonia. While the initial ORR activity in acid medium in rotating disk electrode is similar for both catalysts, the activity in alkaline medium is significantly higher for Fe_{0.5}-NH₃. Time-resolved Fe dissolution reveals a circa 10 times enhanced Fe leaching rate in acidic electrolyte for Fe_{0.5}-NH₃ relative to Fe_{0.5}-Ar. Furthermore, for the former, the leaching rate is strongly enhanced when the electrochemical potential is in the range 0.75–0.3 V vs. RHE. This may explain the reduced stability of ammonia-pyrolyzed Fe-N-C catalysts in operating PEMFCs. In alkaline medium in contrast, Fe_{0.5}-NH₃ is more active and more stable, with minimized Fe leaching during electrochemical operation in load-cycling mode. Operando X-ray absorption spectroscopy measurements in alkaline electrolyte reveals similar trends of the XANES and EXAFS spectra as a function of the electrochemical potential for both catalysts, but the magnitude of change is much less for Fe_{0.5}-NH₃, as evidenced by a Δμ analysis. This is interpreted as a lower average oxidation state of FeN_x moieties in Fe_{0.5}-NH₃ at open circuit potential.

Manuscript submitted January 7, 2019; revised manuscript received April 30, 2019. Published May 17, 2019. *This paper is part of the JES Focus Issue on Advances in Modern Polymer Electrolyte Fuel Cells in Honor of Shimshon Gottesfeld.*

Due to growing concerns related to local and global impacts on the Earth's atmosphere and long-term sustainability of fossil fuels, new ways of producing and using renewable fuels are being explored for both transportation and stationary applications. Hydrogen is a promising fuel that can be produced from water and renewable energy via electrolysis or other means, and back-converted to electric power on demand in high-efficiency fuel cells rather than in low-efficiency combustion engines.¹ While different types of fuel cell technologies exist, the proton exchange membrane fuel cell (PEMFC) has key advantages such as low internal resistance, fast start-up/shutdown and high electric power density.^{2–5} This makes it suitable for small and medium size applications ranging from portable devices to automotive application and distributed electric power production. While high power densities at reasonable energy efficiency can be reached with PEMFC, several drawbacks hold its large-scale commercialization. In particular, the sluggish oxygen reduction reaction (ORR) at the cathode requires the most active catalysts to overcome the kinetic barrier of splitting the double-bond in O₂. To date, all catalysts that meet the ORR activity and stability targets in the acidic PEMFC environment are based on platinum.^{4,5} The low natural abundance in the Earth's crust and geographically-constrained resources of this element raises concerns of cost competitiveness and long-term sustainability of the present PEMFC technology.⁶

Research on non-noble ORR catalysts for PEMFC started ca 50 years ago, and significantly intensified in the past decade.^{7–10} Among catalysts free of platinum group metals (PGMs), metal-nitrogen-carbon catalysts have hitherto shown the highest initial activity toward the ORR in acidic media, especially Fe-N-C catalysts.^{7–12} Compared to Pt-based catalysts, the ORR activity of pyrolyzed Fe-N-C materials is highly dependent on the synthetic path, due to

numerous Fe species that may form at high temperature, ranging from metallic, metal-carbide and metal-nitride Fe particles (often embedded in carbon) to various FeN_x moieties featuring single iron-atoms covalently integrated in the N-doped carbon matrix.^{13–16} Among the preparation methods, the sacrificial metal-organic-framework method has resulted in Fe-N-C catalysts with state-of-the-art activity and power performance in a rotating disk electrode (RDE) and PEMFC, respectively.^{17–19} Characterization by ⁵⁷Fe Mössbauer and X-ray Absorption Spectroscopy (XAS) has revealed that the active sites in Fe-N-C catalysts featuring exclusively atomically-dispersed iron have an FeN₄ structure that is similar to the iron-porphyrin core.^{18,20,21} While Fe-N-C catalysts featuring exclusively Fe-carbide particles embedded in N-doped carbon matrix can also show interesting ORR activity at beginning-of-life (BoL), their stability during load-cycling in acidic medium was recently shown to be insufficient.^{22–24} In contrast, an Fe-N-C catalyst prepared via ramp pyrolysis in inert atmosphere and exclusively comprising FeN₄ moieties showed only 25% loss in activity after 30,000 load cycles at 80°C in inert-gas saturated acidic electrolyte, well above the U.S. Department of Energy target of 40% maximum loss in activity after such an accelerated stress test (AST).²⁴ While such AST protocol cannot capture all degradation mechanisms that will occur in a PEMFC, it is useful in identifying which PGM-free catalysts meet the necessary (but not sufficient) criterion of structural stability when cycled in the cathode potential range and pH environment expected in PEMFC. In particular it is useful to detect demetalation that may occur even in the absence of O₂.

If the ORR activity and stability in acidic medium in RDE setup (stability to load-cycling AST in inert-gas saturated electrolyte) of at least some atomically-dispersed Fe-N-C catalysts is unquestionable, their stability in operating PEMFC has hitherto still been low.^{7,9,17,18,25} This is particularly true for Fe-N-C catalysts prepared via pyrolysis in flowing NH₃, resulting in circa 20–30 times higher BoL activity at 0.9 V in PEMFC than similarly prepared Fe-N-C catalysts but

pyrolyzed in inert atmosphere.^{17,18} After 15–20 h of operation in PEMFC, the current density at 0.5 V obtained with NH₃-pyrolyzed Fe-N-C is however typically halved, while that with Ar-pyrolyzed Fe-N-C undergoes less than 10% decay.^{18,26} Advanced ex situ spectroscopic comparison between an Ar- and a NH₃-pyrolyzed Fe-N-C catalyst revealed no or small difference of Fe coordination, both featuring FeN₄ sites with nearly identical XAS and Mössbauer spectroscopy fingerprints.¹⁸ The only key differences are i) the higher basicity of the catalyst's surface and ii) higher micropore volume for the NH₃-pyrolyzed material. A previous study on another NH₃-pyrolyzed Fe-N-C catalyst revealed that a short immersion in acidic medium (sulphuric acid or perchloric acid) decreased its activity by a factor ten (activity/10), and that this deactivation was partially reversible after the acid-washed catalyst had been subjected to a cleaning treatment at 400°C in inert gas (activity/10 × 5).²⁷ The irreversible activity loss (activity/2) was assigned to metal leaching from weakly bound Fe sites (ca 50% loss of metal upon first acid wash). Since that pristine catalyst contained not only FeN_x moieties but also a significant content of crystalline Fe particles, the metal leached during first acid-wash may have however originated (at least partially) from metallic Fe particles. The reversible deactivation phenomenon (between activity/10 to activity/2) was explained as a protonation of highly basic N-groups (leading to a high turn-over frequency, TOF, of FeN_x moieties) and their charge-neutralization by the electrolyte's counter-anion.²⁷ The latter anion-adsorption event was proposed to decrease the FeN_x site's TOF. Strong support for this reversible deactivation mechanism, not related to any Fe-leaching event, was given by the possibility to recover most of the initial activity of the ammonia-treated Fe-N-C catalyst by removing the adsorbed bisulfate anions (as proven by X-ray photoelectron spectroscopy) during the 400°C treatment. The ORR activity increased from ca only 10% of the initial activity after a short acid wash to ca 50% of the initial activity after removal of the bisulfate anions.²⁷

More recently, the reason for the reduced stability of NH₃-pyrolyzed Fe-N-C catalysts in PEMFC was re-investigated and debated in three follow-up papers.^{25,26,28} Dodelet's group first proposed that the instability of NH₃-pyrolyzed Fe-N-C catalysts in PEMFC is due to oxidation of the carbon surface in micropores, increasing the hydrophilicity and leading to micropore flooding.²⁵ Iron was first claimed to play no role in the deactivation, although Fe coordination and demetallation during operation or post mortem had not been characterized. Choi et al then focused on this micropore-flooding hypothesis²⁸ and could demonstrate that this mechanism could not explain the rapid loss of performance in PEMFC observed with another NH₃-pyrolyzed Fe-N-C catalyst. From polarization curves recorded at different relative humidity and cyclic voltammograms before/after stability test, they concluded that the micropores were partially or completely filled by water already at BoL, and that the rapid performance loss was mainly due to a decrease of the ORR kinetics, and not due to a decay of the mass-transport performance of the cathode layer. While clearly ruling out the micropore flooding hypothesis, their work could not conclusively point what is the mechanism for the rapid decay of the ORR kinetics of NH₃-pyrolyzed Fe-N-C catalysts. Following that work, Dodelet's group agreed that micropore flooding was not the cause for rapid ORR activity decay of their NH₃-pyrolyzed Fe-N-C catalyst as well and, after examination of the Fe content and speciation with Mössbauer spectroscopy following various short-duration PEMFC tests (in the range of 0–20 h), could establish similar trends between a) the current density at 0.6 V vs. duration of operation and b) the relative fraction of Fe present as FeN_x moieties in the cathode as a function of duration of operation in PEMFC, both experiencing a relative decay of ca 50% after 20 h operation.²⁶ The novel hypothesis was that the fast activity decay of NH₃-pyrolyzed Fe-N-C catalyst is due to a demetallation of unstable FeN_x moieties in this material, such moieties being specifically located in micropores. Despite the above-mentioned trend, it must be noted however that the current density at 0.6 V in PEMFC is inappropriate to track changes in the ORR activity, and that the relative decay in ORR activity at 0.8 V after 20 h operation was much higher than 50%, in fact ca 90% (Fig. 4 in Ref. 26). The demetallation from specific FeN_x moieties existing in highly mi-

crosporous Fe-N-C materials may thus explain part of the initial ORR activity decay (e.g. from 1.0 to 0.5 in normalized activity, 1.0 corresponding to BoL activity), but not necessarily all of the decay. It is also possible that the loss of 50% of FeN_x moieties in fact implied that ca 90% of the electrochemically-accessible FeN_x moieties had been leached. Since Mössbauer spectroscopy is a bulk technique, the fact that ca 50% of FeN_x moieties were still present after PEMFC operation does not necessarily imply that those moieties did contribute to the initial ORR activity, if they were not located on the top surface of the carbon matrix.

With no clear path at the moment on how highly-basic N-groups could be stabilized in acidic medium, our scientific interest was first oriented on the degradation mechanisms of inert-gas-pyrolyzed Fe-N-C catalysts with FeN_x moieties as the main active sites. While significantly more durable than NH₃-pyrolyzed catalysts, they also suffer from a slow but steady linear decline with duration of operation in PEMFC.^{26,29} Two main degradation mechanisms of such materials have been identified: (1) irreversible iron leaching from Fe particles imperfectly embedded in carbon or from FeN₄ active sites;³⁰ and (2) reversible degradation induced by the hydrogen peroxide by-product formed during ORR in acidic medium.^{31,32} Mechanism (1) was investigated with online mass-spectrometry and revealed that Fe leaching resulted from carbon corrosion during startup/shutdown AST, while Fe leaching during load-cycling AST mainly originated from Fe particles imperfectly surrounded by a N-C layer. The FeN₄ moieties were mostly stable during load-cycling AST in inert-gas saturated acidic medium, in a broad range of temperature and up to 10,000 cycles.^{24,30,33} The high stability in acidic medium during load-cycling of FeN₄ moieties stood in apparent paradox to their poor durability in operating PEMFC. This conundrum was recently clarified by a study showing that the surface modification of Fe-N-C by hydrogen peroxide does not leach FeN₄ moieties but decreases their TOF.³⁴ This deactivation originates from the chemical reaction of minute amounts of H₂O₂ with the FeN₄ moieties, leading to the formation of reactive oxygen species. These radicals then react with the carbon surface, introducing a high number of oxygen functionalities on the top-surface. From a combined experimental and theoretical investigation, we showed that this decreases i) the electron density at the Fe center and ii) the O₂ binding energy of FeN₄ moieties, resulting in a much decreased single-site TOF.³⁴ Interestingly, the controlled ex situ deactivation of Fe-N-C by hydrogen peroxide revealed that this mechanism is highly pH-dependent, the same protocol but applied in 0.1 M solution of KOH instead of HClO₄ resulting in no deactivation of an Ar-pyrolyzed Fe-N-C catalyst.³⁴ This makes it promising for the application of Fe-N-C catalysts based on FeN₄ moieties in anion exchange membrane fuel cell (AEMFC).^{35–37} In particular, the AEMFC environment might allow combining the highest ORR activity of NH₃-pyrolyzed Fe-N-C catalysts with high durability. Expectation for high durability is supported by i) the stability at high pH of highly-basic N-groups present in NH₃-pyrolyzed catalysts and ii) the lack of peroxide-induced deactivation at high pH on a specific Ar-pyrolyzed Fe-N-C catalyst comprising exclusively FeN₄ sites.

The aims of this study are to assess the site-structure, activity and stability during load-cycling in alkaline electrolyte of a NH₃-pyrolyzed catalyst showing an extremely high ORR activity and exclusively comprising Fe as atomically-dispersed FeN_x moieties. A second Fe-N-C catalyst prepared similarly but obtained via a single pyrolysis in inert gas is also studied, allowing the identification of the effect of pyrolysis atmosphere on the properties of Fe-N-C catalysts. Activity and stability during load-cycling AST was also performed in an acidic electrolyte to assess the effect of electrolyte pH. Activity and stability are measured with rotating disk electrode. Fe coordination and Fe leaching were monitored as a function of the electrochemical potential with operando XAS and a flow cell coupled to online mass-spectrometry, respectively, in order to shed light on activity and stability properties.

This study demonstrates that FeN_x moieties in a NH₃-pyrolyzed Fe-N-C catalyst, while being structurally very similar to those present in the Ar-pyrolyzed Fe-N-C material, show exacerbated

demetallation in acidic medium. Online measurement of Fe dissolution rate shows the Fe demetallation from NH_3 -pyrolyzed Fe-N-C increases when scanning negatively the potential from 1.0 V vs. RHE, to reach a peak of dissolution rate at ca 0.3 V vs. RHE. In alkaline electrolyte, the metal- N_x moieties' stability of Ar- and NH_3 -pyrolyzed Fe-N-C are comparable, and the very highly ORR-active NH_3 -pyrolyzed Fe-N-C material is stable in 0.1 M KOH for several thousands of cycles. Operando XAS of the NH_3 -pyrolyzed Fe-N-C catalyst in alkaline electrolyte shows similar trends as for the Ar-pyrolyzed Fe-N-C catalyst, but with a reduced magnitude of the changes with electrochemical potential. This is interpreted as a lower average oxidation state of the FeN_x moieties at open circuit potential in the NH_3 -pyrolyzed Fe-N-C material compared to the Ar-pyrolyzed Fe-N-C.

Experimental

Synthesis.—Two Fe-N-C catalysts are prepared with the sacrificial metal-organic-framework method, using ZIF-8 (Basolite Z1200, Sigma Aldrich) as support, 1,10-phenanthroline ($\geq 99\%$, Sigma Aldrich) as a secondary source of nitrogen and iron (II) acetate ($\geq 99.99\%$, Sigma Aldrich) as the source of metal. The catalyst precursor is prepared with a weight ratio of 4/1 for ZIF-8/phenanthroline and 0.5 wt% of iron in the complete catalyst precursor. The three precursors are initially mixed using low-energy ball milling at 400 rpm for 2 h 20 min, with 5 minutes pause every 30 minutes of milling. The obtained catalyst precursor is transferred into a quartz boat and inserted in a quartz tube. The first pyrolysis is performed in flash-pyrolysis mode, pre-equilibrating the quartz tube and oven at 1050°C , then pushing the quartz boat and catalyst precursor within 1 min in the heating zone of the furnace with an outer magnet. The pyrolysis duration at 1050°C in flowing Ar is exactly 1 h. The pyrolysis is terminated by opening the split-hinge furnace, removing the quartz tube and letting it cool down at room temperature for 20 minutes. The obtained catalyst is labelled $\text{Fe}_{0.5}\text{-Ar}$. To prepare the NH_3 -pyrolyzed catalyst, $\text{Fe}_{0.5}\text{-Ar}$ is re-pyrolysed with the same flash-pyrolysis mode, but in flowing pure NH_3 and for only 5 minutes at 950°C . The obtained catalyst is labelled $\text{Fe}_{0.5}\text{-NH}_3$.

Electrochemical measurements and time-resolved Fe dissolution rate measurements.—Activity and durability in acidic and alkaline electrolytes are obtained using a RDE set-up (Pine instruments) and either 0.1 M KOH or 0.1 M H_2SO_4 electrolytes. The three-electrode configuration involves a platinum wire immersed in a H_2 -saturated electrolyte compartment, separated from the main compartment by a fritted glass, as a reversible hydrogen electrode (RHE) reference; a graphite plate as a counter electrode and a glassy carbon (GC) rotating disk (5 mm diameter, Pine Research) as a support for the active layer forming the working electrode. The ink is prepared by adding in sequence 5 mg catalyst, 54 μL Nafion (5% perfluorinated resin solution), 744 μL ethanol, 92 μL ultrapure water and sonicating for 1 hour in an ice bath. An aliquot of 7 μL of the ink is pipetted on the GC disk and dried at room temperature, resulting in a catalyst loading of $200 \mu\text{g cm}^{-2}$. The initial activity is measured in O_2 -saturated electrolyte at a scan rate of $1 \text{ mV}\cdot\text{s}^{-1}$ (SP-300, BioLogic Potentiostat) and at rotation rate of 1600 rpm. Due to the low scan rate and low catalyst loading, no correction for the capacitive current is needed. To evaluate the durability of the catalysts in RDE set-up, a load-cycling protocol is applied, comprising 5000 triangular cycles performed at a scan rate of $100 \text{ mV}\cdot\text{s}^{-1}$ in the potential range of 0.6–1.0 V vs RHE and in N_2 -saturated electrolyte. The ORR activity after the AST is measured after re-saturating the solution with O_2 .

The leaching of Fe during short electrochemical cycling, performed either before or after the AST (AST performed in Ar-saturated electrolyte), is investigated in an on-line electrochemical scanning flow cell (SFC) directly connected to an inductively-coupled plasma mass spectrometer (ICP-MS), previously developed by us.^{38–40} It is however challenging to continuously measure Fe leaching over the length of the AST, due to drift of the ICP-MS with time and need for constant recalibration. To measure ^{56}Fe , the ICP-MS (Perkin Elmer, NexION

350) is operated in dynamic-reaction-cell mode, using methane as the reaction gas. The cell is calibrated to both an acidic and alkaline standard solution of iron to ensure maximized detection of ^{56}Fe . Daily calibration of the ICP-MS is done by a four-point calibration curve (0, 0.5, 1.0, 5.0 $\mu\text{g}\cdot\text{L}^{-1}$) of standard iron solutions prepared from Merck Centripur ICP standards ($\text{Fe}(\text{NO}_3)_3$, 1000 $\text{mg}\cdot\text{L}^{-1}$, in 2–3% HNO_3). As an internal standard, we use ^{58}Co (Merck Centripur, $\text{Co}(\text{NO}_3)_2$, 1000 $\text{mg}\cdot\text{L}^{-1}$, in 2–3% HNO_3) diluted to 50 $\mu\text{g}\cdot\text{L}^{-1}$ in HNO_3 (0.15 $\text{mol}\cdot\text{L}^{-1}$) to ensure full acidification of the electrolyte in a y-connector before its introduction in the ICP-MS. The SFC consists of a three-electrode setup using a Ag/AgCl (Metrohm, 3 M KCl) reference electrode, a graphite rod counter electrode and a GC RDE as a working electrode, on which the catalyst is drop cast. A positioning stage (Physik Instrumente, M-403.6 DG) is used to approach individual catalyst spots on the working electrode. Stability measurements are conducted in alkaline (99.99%, Suprapur, NaOH, 0.05 $\text{mol}\cdot\text{L}^{-1}$) as well as in acidic (Suprapur, 0.05 $\text{mol}\cdot\text{L}^{-1}$ H_2SO_4) electrolyte. The potentiostat (Gamry, Reference 600) as well as purging gases and the positioning stage is controlled by a custom LabVIEW software. The catalyst ink is prepared from the Fe-N-C catalyst, Nafion (5% perfluorinated resin solution) and water, with a mass ratio of catalyst/dry-ionomer of 4 and a catalyst concentration of 3.3 $\text{g}\cdot\text{L}^{-1}$ in the liquid ink. An aliquot of 2.75 μL is deposited on the GC, resulting in a catalyst loading of $400 \mu\text{g}\cdot\text{cm}^{-2}$. Such a high loading is necessary to reach a sufficient signal-to-noise ratio in the ICP-MS measurements. This is due to the aforementioned interference of the $^{40}\text{Ar}^{16}\text{O}$ dimers and high background noise of iron in alkaline solution. For Fe-leaching measurement before and after the AST, the latter is conducted in a separate Teflon RDE-cell containing 100 mL electrolyte, and the RDE tip is then quickly transferred from the Teflon cell to the SFC set-up, with the catalyst still wetted by electrolyte. The RDE cell used for the AST consists of four individual compartments, one each for the three electrodes and for the purging tube. The counter and reference electrodes are the same as in the SFC setup.

Physico-chemical characterization.—The pristine catalysts are characterized with ^{57}Fe Mössbauer spectroscopy at room temperature. To this end, ^{57}Fe -enriched catalysts are used, prepared identically as the ones otherwise investigated in this study, except for the use of ^{57}Fe acetate during their synthesis. Mössbauer spectra are measured at room temperature with a ^{57}Co :Rh source. The measurements are carried out in triangular velocity waveform using NaI scintillation detector for γ -rays. The velocity calibration is done with an α -Fe foil. A mass of 30 mg of ^{57}Fe -enriched $\text{Fe}_{0.5}\text{-Ar}$ and $\text{Fe}_{0.5}\text{-NH}_3$ powders are necessary for a proper signal-to-noise resolution.

The pristine catalysts are also characterized with XAS in both ex situ and operando conditions. The XAS spectra are collected at SAMBA beamline (synchrotron SOLEIL) at the Fe K-edge using a double crystal Si 220 monochromator and a Canberra 35-elements germanium detector for operando acquisition in fluorescence mode. The catalyst ink (10 mg catalyst, 100 μL 5% Nafion solution and 50 μL ultrapure H_2O) is prepared via ultrasonication, and 50 μL is deposited on *circa* 3 cm^2 circular area of a larger conductive carbon foil, resulting in a catalyst loading of *circa* 1 mg cm^{-2} .⁴¹ The carbon foil is then inserted in a three-electrode cell, 0.1 M KOH electrolyte is added and the three electrodes are connected, using Pt-wire counter electrode and a Hg/HgO reference electrode. Note that all potentials are however reported in V vs. RHE in this work. Air is continuously bubbled in the electrolyte during the measurements. The operando XAS spectra are collected at open circuit potential (OCP), 0.2, 0.4, 0.6, 0.8 and 1.0 V vs. RHE. Ex situ spectra were collected in transmission geometry on pellets of 1 mm diameter using Teflon powder as a binder.

To measure the specific surface area of carbon in the catalysts, sorption isotherms of N_2 are measured in liquid nitrogen (77 K) with a Micromeritics, ASAP 2020 instrument. The sample is previously cleaned at 200°C for 5 h in flowing nitrogen. The specific surface area is determined by the multipoint Brunauer-Emmett-Teller (BET) method.

Figure 1. RDE determination of the ORR activity of $\text{Fe}_{0.5}\text{-Ar}$ (a, b) and $\text{Fe}_{0.5}\text{-NH}_3$ (c, d) in acidic (gray curves) and alkaline (purple curves) electrolyte before (filled symbols) and after (empty symbols) the load-cycling AST. Polarization curves were measured in O_2 -saturated electrolyte at a scan rate of 1 mV s^{-1} , a rotation rate of 1600 rpm and a catalyst loading of $200 \mu\text{g}\cdot\text{cm}^{-2}$. The curves are not corrected for ohmic loss. The AST has been conducted in N_2 -saturated electrolyte, in a potential range of 0.6–1.0 V vs RHE, with a scan rate of 100 mV s^{-1} for 5000 cycles. The semi-logarithmic Tafel plots on the left handside have been obtained from the polarization curve by applying the Koutecky-Levich equation, taking the value of diffusion-limited current density as the current density at 0.4 V vs. RHE.

Results

Initial ORR activity and ex situ spectroscopic characterization.—

The ORR activity before and after the AST is shown in Figure 1 in linear- and semi-logarithmic scales, for $\text{Fe}_{0.5}\text{-Ar}$ (Figs. 1a–1b) and $\text{Fe}_{0.5}\text{-NH}_3$ (Figs. 1c–1d). In each sub-figure, the measurements performed in alkaline electrolyte are shown as purple curves while those performed in acidic electrolyte are plotted in gray color. The curves before and after AST are identified with filled and open symbols, respectively. Before the AST, $\text{Fe}_{0.5}\text{-Ar}$ shows a similar activity in both electrolytes (Fig. 1b, curves with filled symbols), with ORR mass activity at $0.9 \text{ V}_{\text{RHE}}$ of 0.35 and $0.25 \text{ A}\cdot\text{g}^{-1}$ in alkaline and acidic electrolytes, respectively. A slight difference is visible only at low-potential, with a less defined diffusion-limited current density in acidic medium (Figures 1a, filled gray symbols).

A distinct behavior appears for $\text{Fe}_{0.5}\text{-NH}_3$, characterized with a much higher initial activity in alkaline vs. acidic electrolyte (Figures 1c–1d, filled purple vs. filled gray symbols), with ORR mass activity at 0.9 V vs. RHE of 4.6 and $0.5 \text{ A}\cdot\text{g}^{-1}$, respectively. The former is among the highest reported value of the ORR activity in alkaline medium for PGM-free catalysts.^{42–46} Its lower initial activity in acidic than in alkaline electrolyte can mostly be assigned to a fast protonation of highly-basic nitrogen groups followed by anion-adsorption on positively-charged $[\text{NH}]^+$ groups, which had been previously shown, on other NH_3 -pyrolyzed Fe-N-C catalysts, to divide the activity by a factor 5 to 10.^{27,45,47} High initial activity of NH_3 -pyrolyzed Fe-N-C

catalysts in acidic liquid-electrolyte could previously be achieved only with high catalyst loading and optimized Nafion/catalyst ratio.⁴⁷ It is anticipated that these two parameters allow a short time protection of the highly basic N-groups from the liquid acidic electrolyte. With the present experimental conditions (low scan rate and low catalyst loading), the high ORR activity of $\text{Fe}_{0.5}\text{-NH}_3$ cannot be captured in acidic liquid-electrolyte because the highly basic N-groups were likely protonated and charge-neutralized even before the first polarization curve was recorded. The surface state of $\text{Fe}_{0.5}\text{-NH}_3$ in acidic medium is then similar to that of $\text{Fe}_{0.5}\text{-Ar}$, explaining similar initial ORR activities in acid (compare filled gray symbols in Fig. 1b and Fig. 1d). The slightly higher initial ORR mass activity in acid of $\text{Fe}_{0.5}\text{-NH}_3$ vs. $\text{Fe}_{0.5}\text{-Ar}$ (0.50 vs. $0.25 \text{ A}\cdot\text{g}^{-1}$ at 0.9 V vs. RHE, see Table I) can be explained by its higher BET specific area, 970 vs. $635 \text{ m}^2\text{g}^{-1}$.

A second possibility to explain the lower initial activity of $\text{Fe}_{0.5}\text{-NH}_3$ in acid vs. alkaline electrolyte is that (at least some) FeN_x moieties after NH_3 pyrolysis are intrinsically different from those after Ar-pyrolysis and, while being more active for ORR (regardless of which pH), would also be less stable in acidic medium. It might be that such highly-active FeN_x moieties were leached in acidic medium even before completing the acquisition of the first polarization curve. Evidence for increased Fe leaching with the $\text{Fe}_{0.5}\text{-NH}_3$ catalyst in acidic medium is reported in the section entitled electrochemical stability and operando iron leaching study. We also note that the contribution of N-groups (not binding Fe) to the overall initial ORR activity of those two catalysts can be neglected. Two reference materials prepared

Table I. Mass activity at 0.9 V vs. RHE before and after the AST for Fe_{0.5}-Ar and Fe_{0.5}-NH₃ in acidic and alkaline electrolytes. The AST comprises 5000 cycles between 0.6 V and 1.0 V vs. RHE, in N₂-saturated 0.1 M KOH at room temperature. The catalyst loading was 200 µg·cm⁻².

Catalyst ↓	Mass activity / A g ⁻¹			
	Acidic electrolyte		Alkaline Electrolyte	
	Before AST	After AST	Before AST	After AST
Fe _{0.5} -Ar	0.25	0.25 (−0%)	0.35	0.55 (+ 57%)
Fe _{0.5} -NH ₃	0.50	0.35 (−30%)	4.60	4.15 (−10%)

similarly as Fe_{0.5}-Ar and Fe_{0.5}-NH₃ but without addition of Fe acetate were studied in RDE and their initial ORR activity in 0.1 M KOH at 0.9 V vs. RHE is 0.03 and 0.57 A·g⁻¹, respectively. This is circa 10 times lower than the activity of corresponding Fe-NC materials, 0.35 and 4.60 A·g⁻¹ (Table I). The difference would be even larger in acidic medium.

In order to characterize the active-site structure in Fe_{0.5}-NH₃ and Fe_{0.5}-Ar, we first resorted to ex situ spectroscopic characterization. The ex situ ⁵⁷Fe Mössbauer spectra could not reveal any significant difference between the two catalysts (Figures 2a–2b and supporting Table S1). They were fitted with two doublets D1 and D2, each one having similar Mössbauer parameters for both catalysts and being present in similar ratio. These doublets are assigned to atomically-dispersed FeN_x moieties.¹⁸ Similar Mössbauer spectra imply that the local Fe coordination and site geometry, up to two coordination spheres, are similar in both catalysts. Further identification of the active-site structure was performed using XAS. Figure 2c shows the ex situ X-ray absorption near-edge structure (XANES) spectra of Fe_{0.5}-NH₃ (circle symbols) and Fe_{0.5}-Ar (solid curve), that are characteristic for Fe-N-C catalysts free of metallic particles.¹⁸ The absence of a strong signal at ca 2.2 Å (Fe-Fe bond distance in metallic and metal-nitride par-

ticles, uncorrected for phase shift) in the Fourier transform (FT) of the EXAFS spectra of both Fe_{0.5}-Ar and Fe_{0.5}-NH₃ indicates that both catalysts are free of Fe-based particles, or that the amount of particles is below the XAS detection limit, which is approximately 3% relative to the total amount of Fe in the catalysts (Figure 2d). The absence in the XANES spectra of the pre-edge peak at 7118 eV, characteristic for unpyrolyzed Fe(II) phthalocyanine (FeN₄ square-planar structure with identical Fe-N bond distances), reveals a broken D_{4h} symmetry of the FeN_x moieties. This may be due to structural disorder or existence of ferric moieties with an axial ligand such as O₂. The latter case is particularly possible when recording ex situ spectra of catalysts in their resting state in air environment. The white line intensity is slightly stronger for Fe_{0.5}-Ar than Fe_{0.5}-NH₃. This may be interpreted as a higher coordination number in the first coordination sphere surrounding Fe (either N, C or O atoms). This hypothesis is supported by the stronger signal of the first peak (at ca 1.4 Å) in the FT-EXAFS spectra for Fe_{0.5}-Ar vs. Fe_{0.5}-NH₃ (Figure 2d). Such ex situ changes may be assigned to a stronger FeN₄-O₂ interaction ex situ for Fe_{0.5}-Ar, possibly due to a higher average oxidation state of Fe in Fe_{0.5}-Ar vs. Fe_{0.5}-NH₃. In the latter, a lower oxidation state of Fe may be expected due to the presence of Lewis-base (highly basic) nitrogen

Figure 2. Ex situ spectroscopic characterization of Fe_{0.5}-NH₃ and Fe_{0.5}-Ar. ⁵⁷Fe Mössbauer transmission spectra (top) for a) Fe_{0.5}-Ar and b) Fe_{0.5}-NH₃. XAS spectroscopic characterization at the Fe K-edge (bottom) by c) XANES and d) EXAFS. The spectra were recorded in air at room temperature. The distance in the FT-EXAFS spectra is not corrected for phase-shift.

Figure 3. Operando XAS characterization of $\text{Fe}_{0.5}\text{-Ar}$ (a-b) and $\text{Fe}_{0.5}\text{-NH}_3$ (c-d) in O_2 -saturated 0.1 M KOH electrolyte. XANES (left-handside) and FT-EXAFS (right-handside) was recorded between 0.2 and 1.0 V vs. RHE. The legend indicates the potential (in V vs RHE) at which each spectrum was recorded. The insets in subfigures a and c show the $\Delta\mu$ spectra, obtained by subtracting the normalized XANES spectrum at a given potential to the spectrum recorded at 0.2 V vs. RHE.

groups, if some of those groups are directly involved in Fe cations ligation.

Operando spectroscopic characterization.—In order to investigate whether the small differences observed ex situ with XANES and FT-EXAFS spectra of both catalysts remained, disappeared or were exacerbated during the ORR in alkaline medium, we performed operando XAS. The XANES and EXAFS spectra were recorded in alkaline electrolyte between 0.2 and 1.0 V vs. RHE, covering all regions of the RDE polarization curves (Supporting Figure S1). Figure 3 shows the operando XANES spectra (left-handside) and FT-EXAFS spectra (right-handside) for $\text{Fe}_{0.5}\text{-Ar}$ (top) and $\text{Fe}_{0.5}\text{-NH}_3$ (bottom). For $\text{Fe}_{0.5}\text{-Ar}$, both the operando XANES and FT-EXAFS spectra reveal large changes with the electrochemical potential (Figures 3a–3b). The change of the XANES spectra with potential observed here for $\text{Fe}_{0.5}\text{-Ar}$ in alkaline medium is similar to that reported by us for the same catalyst in acidic medium.⁴¹ The magnitude of change is however ca twice smaller in alkaline vs. acidic medium for $\text{Fe}_{0.5}\text{-Ar}$, as can be seen by comparing the $\Delta\mu$ spectra (compare the inset of Fig. 3a in this work with the inset of Fig. 4b in Ref. 41). In the ORR potential region, the FeN_4 -moieties in $\text{Fe}_{0.5}\text{-Ar}$ undergo a structural change, as revealed by the complex change and existence of isobestic points at 7130.5 and 7156.4 eV in the set of XANES spectra.

These isobestic points support the existence of at least two Fe-site geometries, whose fraction switches gradually from 0 to 1 across the potential range of 0.2 to 1.0 V vs. RHE. This observation has also been reported, but only in acidic electrolyte hitherto, for other Fe-N-C materials^{19,48,49} and interpreted as a change from in-plane FeN_4 to out-of-plane FeN_4 configuration as a function of potential. The operando FT-EXAFS (Figure 3b) also support a structural change, with a decreasing signal intensity at 1.4 Å with decreasing potential.

This can be interpreted as the presence of oxygen adsorbates (O_2 , OH and H_2O) strongly adsorbed on FeN_4 sites at high potential, and their absence or elongated Fe-O bond distance at low potential. Those spectroscopic changes were reversible, similar spectra being recorded at a given potential, when scanning down and then up the potential from 1.0 to 0.2 V and then back up to 1.0 V.

The operando XANES spectra of $\text{Fe}_{0.5}\text{-NH}_3$ in alkaline electrolyte reveal much smaller changes with electrochemical potential, as compared to changes observed for $\text{Fe}_{0.5}\text{-Ar}$ in the same electrolyte (compare Figure 3c vs. Figure 3a). The $\Delta\mu$ spectra (inset of Fig. 3c) reveals a trend that is however comparable to the $\Delta\mu$ signals observed with $\text{Fe}_{0.5}\text{-Ar}$ in alkaline electrolyte (inset of Fig. 3a), but with ca twice lower magnitude of change. The smaller spectral changes with electrochemical potential observed for $\text{Fe}_{0.5}\text{-NH}_3$ vs. $\text{Fe}_{0.5}\text{-Ar}$ may appear at first counterintuitive, since the former has a higher BET area and expectedly a higher exposure of Fe-sites to the top surface and to the electrolyte. The smaller spectral changes with potential observed for $\text{Fe}_{0.5}\text{-NH}_3$ must therefore be assigned to a distinct environment of Fe-sites in $\text{Fe}_{0.5}\text{-NH}_3$ compared to $\text{Fe}_{0.5}\text{-Ar}$, in line with their much different ORR activities in alkaline electrolyte (Figure 1).

In line with the operando XANES spectra, the corresponding FT-EXAFS spectra of $\text{Fe}_{0.5}\text{-NH}_3$ are almost unchanged with potential (Fig. 3d). The trend of the signal intensity at 1.4 Å with electrochemical potential is the same as for $\text{Fe}_{0.5}\text{-Ar}$ (decreasing signal with decreasing potential), but the magnitude of the change is also much smaller. It is in fact only significant at the lowest potential studied, namely 0.2 V vs. RHE.

Coming back to the initial question whether the small differences observed ex situ with XANES and FT-EXAFS spectra of both catalysts remained or disappeared in operando, the direct comparison of the XANES and EXAFS spectra of both catalysts at low potential

Figure 4. Time-resolved potential (top) dissolution rates (middle) and totally dissolved amount (bottom) of iron from $\text{Fe}_{0.5}\text{-Ar}$ (a) and $\text{Fe}_{0.5}\text{-NH}_3$ (b) measured in oxygen saturated electrolyte according to the color scheme of Figure 1. Note the different range of dissolution values in the Y-axis for a) and b). The contact dissolution peak is marked with an asterisk in the upper panels. Dissolution rates after AST in Ar-saturated electrolyte have been omitted for clarity in the middle panels since they are negligible.

(0.2 V vs. RHE, Figure S2) reveals that the spectroscopic signatures are almost identical. Thus, the two catalysts differ in ex situ conditions or in situ at high electrochemical potential, but the differences become smaller as the potential is lowered, and become negligible at 0.2 V vs. RHE. This supports the hypothesis that, in ex situ conditions, Fe is in a higher oxidation state in $\text{Fe}_{0.5}\text{-Ar}$ than in $\text{Fe}_{0.5}\text{-NH}_3$, and binds more O_2 or oxygen adsorbates. In operando conditions, the difference progressively vanishes as the electrochemical potential is reduced (ferric moieties turning into ferrous moieties in $\text{Fe}_{0.5}\text{-Ar}$, becoming then in a similar state as $\text{Fe}_{0.5}\text{-NH}_3$).

Electrochemical stability and operando iron leaching study.—

The stability of $\text{Fe}_{0.5}\text{-Ar}$ and $\text{Fe}_{0.5}\text{-NH}_3$ catalysts was studied in both acidic and alkaline electrolytes. Table I summarizes the activity observed before and after the 5000 load-cycle AST. Starting with $\text{Fe}_{0.5}\text{-Ar}$ in alkaline medium, an activity increase from 0.07 to 0.11 mA cm^{-2} at 0.9 V vs. RHE can be seen after 5000 load-cycles in N_2 -saturated solution (purple curves in Figs. 1a–1b). Similarly, also $\text{Fe}_{0.5}\text{-NH}_3$ shows high stability in alkaline electrolyte, with very slight decay in activity at 0.9 V vs. RHE (from 0.92 to 0.83 mA cm^{-2} , see purple curves in Figs. 1c–1d). In acidic medium, no activity loss was observed for $\text{Fe}_{0.5}\text{-Ar}$, but a significant loss observed for $\text{Fe}_{0.5}\text{-NH}_3$, with a relative decrease of about 24% (Table I).

We attribute this reduced activity following AST in N_2 -saturated electrolyte to a loss of a fraction of the active centers, i.e. FeN_4 or only Fe cations from FeN_4 moieties, from the nitrogen-doped carbon network. Since the AST was performed in N_2 -saturated electrolyte, no ORR occurred during the AST and we can exclude a degradation or deactivation due to hydrogen peroxide or reactive oxygen species formed from peroxide and FeN_x sites, which was recently demonstrated to cause a main deactivation of Fe-N-C catalysts in acidic medium.³⁴ To show this loss of iron in situ, we conducted SFC-ICP-MS measurements. Figure 4 summarizes the operando Fe leaching measurements where we applied the same potential-scan protocol (upper plot) to

$\text{Fe}_{0.5}\text{-Ar}$ and $\text{Fe}_{0.5}\text{-NH}_3$ in oxygen-saturated electrolyte. The electrode was first contacted by the SFC (corresponding time marked with * in the graph, $t \sim 250$ s) at open circuit potential (OCP). The applied electrochemical potential protocol is then 20 cyclic voltammograms (CVs) in the range 1.0 to 0.6 V vs. RHE at a scan rate of 100 mV s^{-1} , a potential range typically occurring during the ORR in fuel cell devices. Another chronoamperometry at 1.0 V was recorded for 200 s, before applying one CV at a low scan rate of 2 mV s^{-1} from 1.0 V down to 0.0 V vs. RHE, and back up to 1.0 V vs. RHE to identify in more detail the potential-dependence of Fe dissolution.

For each catalyst considered separately, Figure 4 clearly identifies higher Fe dissolution rates in acid than in alkaline electrolyte, especially during the slow CV. We first discuss the transient release of Fe occurring when the SFC contacts the electrode with the electrolyte (time marked with an asterisk), leading to an initial loss of iron. For $\text{Fe}_{0.5}\text{-Ar}$, this initial loss is similar in both electrolytes (Fig. 4a, middle panel), while for $\text{Fe}_{0.5}\text{-NH}_3$ the dissolution rate in acid medium is more than double that in alkaline electrolyte (Fig. 4b, middle panel). Comparing the contact dissolution in acidic medium, the peak dissolution rates are ca 1.0 and 0.4 $\text{ng Fe cm}^{-2} \text{s}^{-1}$ for $\text{Fe}_{0.5}\text{-NH}_3$ and $\text{Fe}_{0.5}\text{-Ar}$, respectively. After 400 s at OCP in acid medium, the Fe dissolution rate became $< 0.15 \text{ ng Fe cm}^{-2} \text{s}^{-1}$ for $\text{Fe}_{0.5}\text{-Ar}$ but remained significant ($\sim 1.0 \text{ ng Fe cm}^{-2} \text{s}^{-1}$) and quite constant for $\text{Fe}_{0.5}\text{-NH}_3$. The cumulative Fe dissolution of $\text{Fe}_{0.5}\text{-NH}_3$ at that stage is however restricted to ca 0.5 $\mu\text{g Fe cm}^{-2}$ (Fig. 4b, lower panel), much lower than the total amount of Fe in the catalyst layer (ca 2.5 wt% Fe in $\text{Fe}_{0.5}\text{-NH}_3$, leading to ca 10 $\mu\text{g Fe cm}^{-2}$). It is therefore unlikely that the lower activity measured for $\text{Fe}_{0.5}\text{-NH}_3$ in acid vs. alkaline originates from a very fast dissolution of iron. In alkaline medium, the curves of Fe dissolution rate vs. time of both catalysts are nearly superimposed (from immersion to OCP hold, time 250 to 850 s on x-axis), with a peak value of Fe dissolution rate of ca 0.5 $\text{ng Fe cm}^{-2} \text{s}^{-1}$, quickly decreasing (only ca 0.1 $\text{ng Fe cm}^{-2} \text{s}^{-1}$ before starting the fast CVs). Therefore, a trend is observed that $\text{Fe}_{0.5}\text{-Ar}$ is more stable than $\text{Fe}_{0.5}\text{-NH}_3$, and

Figure 5. Percentage of initial iron remaining in the catalyst as a function of time. The electrochemical potential applied as a function of time is the same as that shown in Figure 4.

that alkaline environment leads to lower dissolution rate than acidic medium.

The subsequent fast 20 CV scans increased the Fe release rate in acidic medium, especially for $\text{Fe}_{0.5}\text{-NH}_3$ (increasing to $1.5 \text{ ng}_{\text{Fe}}\cdot\text{cm}^{-2}\cdot\text{s}^{-1}$), while it had no impact on the Fe dissolution rate in alkaline medium. Note that, due to the high scan rate used during the 20 CVs, the effect of scanning up or down the potential cannot be distinguished, and only a lump Fe dissolution rate is observed.

The time-resolved Fe dissolution rate during the subsequent slow potential scan then allows us identifying at which potential Fe is dissolved. In sulfuric acid, the onset of Fe dissolution while scanning the potential from 1 V down to 0 V occurs at ca 0.75 V vs. RHE, and the peak of dissolution rate occurs at ca 0.2–0.3 V vs. RHE, for both catalysts. The intensity of the peak of Fe dissolution is however 10 times higher for $\text{Fe}_{0.5}\text{-NH}_3$ vs. $\text{Fe}_{0.5}\text{-Ar}$. At potentials $E < 0.2$ V vs. RHE, the Fe dissolution rate decreases for both catalysts, and remains very low also during the positive-going scan from 0.0 V to 1.0 V vs. RHE. For $\text{Fe}_{0.5}\text{-NH}_3$, the cumulative Fe amount leached after the slow CV reaches ca $2 \mu\text{g}\cdot\text{cm}^{-2}$, representing about 50% of the total Fe content initially present (Fig. 4b, lower panel). Regarding the Fe release rate during the slow CV in alkaline electrolyte, there is no significant effect of the electrochemical potential in the negative-going branch of the scan, while reverting the scan direction from 0.0 V and upwards resulted in increased Fe dissolution rate for $\text{Fe}_{0.5}\text{-NH}_3$ but unmodified Fe dissolution rate for $\text{Fe}_{0.5}\text{-Ar}$. These experiments were repeated multiple times, and showed reproducible trends.

While Figure 4 informs on the electrochemical conditions in which Fe is dissolved, Figure 5 quantitatively shows how much Fe from the catalysts was dissolved as a function of time in the SFC-ICP-MS protocol before the AST. The y-axis shows the %Fe remaining in the catalyst relative to the initial Fe content. The cumulative dissolved Fe content was obtained from the integral of the curves shown in the lower panels of Figure 4 while the total Fe content in each electrode was derived from i) the fixed Fe-N-C catalyst loading value and the exact geometric area investigated by SFC-ICP-MS (verified each time by a microscope) and ii) the knowledge of the initial Fe content in each catalyst. The latter were measured by ICP-MS on the catalyst powders to be 1.45 wt% for $\text{Fe}_{0.5}\text{-Ar}$ and 1.57 wt% for $\text{Fe}_{0.5}\text{-NH}_3$. Figure 5 shows that the absolute Fe dissolution is restricted for $\text{Fe}_{0.5}\text{-Ar}$ (at both pH) and for $\text{Fe}_{0.5}\text{-NH}_3$ at high pH (5 to 10% relative Fe content is dissolved after 20 fast CVs and a slow scan) while for $\text{Fe}_{0.5}\text{-NH}_3$ at acidic pH, more than 50% of the initial Fe content present in the active layer was dissolved after the same time.

These time-resolved Fe dissolution data reveal that the Fe-based sites in $\text{Fe}_{0.5}\text{-NH}_3$ are less stable in acidic medium than those present in $\text{Fe}_{0.5}\text{-Ar}$, while in alkaline medium the stability of $\text{Fe}_{0.5}\text{-NH}_3$ is

as good, or even better, than that of $\text{Fe}_{0.5}\text{-Ar}$. While the data might be interpreted by assuming that a much higher fraction of all FeN_x sites are exposed to the electrolyte in $\text{Fe}_{0.5}\text{-NH}_3$ than in $\text{Fe}_{0.5}\text{-Ar}$, this assumption should have resulted in a slightly increased Fe dissolution for $\text{Fe}_{0.5}\text{-NH}_3$ in alkaline electrolyte compared to that for $\text{Fe}_{0.5}\text{-Ar}$ in the same electrolyte. This is however not observed. The operando XAS data are also not in support of an increased fraction of FeN_x sites being exposed to the electrolyte in $\text{Fe}_{0.5}\text{-NH}_3$ (smaller magnitude of change for the XANES and EXAFS spectra with potential than for $\text{Fe}_{0.5}\text{-Ar}$). Thus, the electrolyte-exposed FeN_x sites in $\text{Fe}_{0.5}\text{-NH}_3$ seem to be intrinsically less stable in acidic medium than those in $\text{Fe}_{0.5}\text{-Ar}$.

Discussion

The operando XANES and EXAFS data in alkaline electrolyte reveal that the catalyst $\text{Fe}_{0.5}\text{-NH}_3$ experiences less change of its site geometry and Fe oxidation state as a function of the electrochemical potential, as compared to $\text{Fe}_{0.5}\text{-Ar}$. This is assigned to a lower average oxidation state of Fe cations in FeN_x moieties in the resting state for $\text{Fe}_{0.5}\text{-NH}_3$ than for $\text{Fe}_{0.5}\text{-Ar}$. These fine differences between FeN_4 sites in Ar-pyrolyzed and NH_3 -pyrolyzed catalysts are revealed here for the first time by operando XAS, and can explain the higher TOF at high potential for ORR of $\text{Fe}_{0.5}\text{-NH}_3$ relative to $\text{Fe}_{0.5}\text{-Ar}$. The lower average oxidation state of Fe in NH_3 -pyrolysed catalysts may be a consequence of the presence of nitrogen groups with Lewis basicity. It can be reasonably proposed that the involvement of highly basic nitrogen groups in Fe ligation in $\text{Fe}_{0.5}\text{-NH}_3$ results in increased electron density at the Fe centers, increased O_2 binding and also introduces the possibility to immobilize protons near the Fe centers, which could reduce the energy barrier during the rate determining step of the ORR. However, if highly basic nitrogen groups are directly involved in the coordination of all or some FeN_x moieties, it can be expected that such moieties will be stable only in alkaline electrolyte, and not in acidic medium. The operando Fe leaching measurements support this hypothesis, with increased Fe leaching specifically observed for $\text{Fe}_{0.5}\text{-NH}_3$ in acidic medium. The instability in acidic medium of some FeN_x moieties present in $\text{Fe}_{0.5}\text{-NH}_3$ may thus be assigned to the higher basicity of N-groups that ligate some of the iron cations. Upon their protonation in acidic medium, the covalent bond that previously existed between such Fe cations and nitrogen is broken or weakened, and the iron cations are dissolved in the electrolyte.

It is however unresolved from the dissolution data whether such unstable FeN_x moieties in acidic medium account for the vast majority of the ORR activity of pristine $\text{Fe}_{0.5}\text{-NH}_3$, or both stable and unstable FeN_x moieties co-exist in comparable amount. The latter hypothesis is more likely. Due to the disorder of the system formed during high-temperature pyrolysis in NH_3 , one might expect that two types of moieties coexist, i) FeN_x moieties with Fe ligated by at least one highly-basic nitrogen group, and ii) FeN_x moieties with Fe ligated only by nitrogen groups with low pKa value (non-protonating in pH 1). The existence of this mixed system of FeN_x moieties would explain the irreversible loss of ORR activity experienced by NH_3 -pyrolyzed Fe-N-C catalysts after an acid-wash but also the fact that the very low ORR activity after acid-wash (activity / initial activity = 0.1) can be recovered to about 0.5 of the initial activity after a mild re-heat-treatment at 300°C (that removes anions and restores the N-groups in a non-protonated state).²⁷ Bringing further complexity, the online Fe dissolution data reveals here that the Fe leaching from $\text{Fe}_{0.5}\text{-NH}_3$ in acid medium is significantly enhanced when the electrochemical potential is < 0.75 V vs. RHE, and almost peaks at 0.5 V vs. RHE, a potential close to the one often chosen during stability testing of PGM-free cathode catalysts in PEMFC.

Thus, while there is no doubt that the nitrogen protonation and anion-binding phenomenon reduces the high activity of NH_3 -pyrolysed Fe-N-C catalysts in liquid acid electrolyte in RDE set-up, it is unclear whether this effect is responsible for the fast decay of NH_3 -pyrolysed Fe-N-C catalysts during the first 10–15 h of operation in PEMFC. The online Fe dissolution data presented here suggest that the Fe dissolution rate of NH_3 -pyrolysed Fe-N-C catalysts in acid medium

may be very fast at cathode potentials of 0.3-0.6 V vs. RHE. The circa 10 x faster Fe leaching rate from Fe_{0.5}-NH₃ than from Fe_{0.5}-Ar in liquid acid medium in this potential range is in line with the relative degradation rate of Fe_{0.5}-NH₃ vs Fe_{0.5}-Ar in PEMFCs. Further study exploring the potential-dependence and atmosphere-dependence (O₂, air or simply N₂) of the performance degradation of Fe_{0.5}-NH₃ during potentiostatic control of PEMFC cathodes, combined with Fe dissolution measurements may strengthen this hypothesis.

The antagonism between ORR activity and stability of Fe_{0.5}-NH₃ revealed here in acid medium does not exist in alkaline electrolyte, where high activity and high stability are simultaneously met. This supports the idea that highly-basic N-groups are at the root of the high ORR activity of FeN_x moieties in ammonia-pyrolyzed Fe-N-C catalysts. Such catalysts are therefore proper candidates for replacing Pt-based catalysts in AEMFCs.

Conclusions

Two Fe-N-C catalysts comprising only atomically-dispersed FeN_x moieties were prepared, differing only in the fact that the second catalyst (Fe_{0.5}-NH₃) was obtained by subjecting the first one (Fe_{0.5}-Ar) to a short pyrolysis in ammonia. While the initial ORR activity in acid medium in RDE setup is similar for both catalysts, the activity in alkaline medium is significantly higher for Fe_{0.5}-NH₃. Operando XAS measurements in alkaline electrolyte reveals similar trends of the spectra as a function of the electrochemical potential for both catalysts, but the magnitude of change is much less for Fe_{0.5}-NH₃, as evidenced by a $\Delta\mu$ analysis. Accelerated stress tests in alkaline and acidic electrolyte revealed that the ORR activity of both catalysts was very stable in alkaline electrolyte, while some activity decay is observed for both catalysts in acidic electrolyte after 5000 cycles. Time-resolved Fe dissolution combined with previous literature studies point that the lower ORR activity of Fe_{0.5}-NH₃ in acid vs. alkaline liquid electrolyte is the outcome of two phenomena, i) the leaching of a fraction of acid-unstable FeN_x moieties, and ii) the protonation and charge-neutralization by counter-anions of the electrolyte of highly-basic N-groups. Overall, ammonia pyrolysis of Fe-N-C catalysts is shown to result, in alkaline medium, in high ORR activity of atomically-dispersed FeN_x moieties, high ORR durability and minimized Fe leaching during electrochemical operation in load-cycling mode. In acid electrolyte, the ammonia pyrolysis of Fe-N-C catalysts results in circa 10 times enhanced Fe leaching relative to the reference inert-gas pyrolyzed catalyst, with a Fe leaching rate that is strongly enhanced when an electrochemical potential in the range 0.75 to 0.3 V vs. RHE is applied. This may explain the recognized reduced stability of ammonia-pyrolyzed Fe-N-C catalysts in operating PEMFCs.
