Keywords

nanoparticles, aerogel, sol-gel process, *tert*-butanol/water, structured solvent, surfactant-less microemulsion

Abstract

Soft matter structure is a useful tool for the preparation of well-structured inorganic materials. Here, we report a strategy using a structured solvent based on binary mixtures as directing agent for silica nanoparticles in aerogel elaboration. Binary mixtures involving water/EtOH and water/*tert*-butanol have been respectively chosen as representatives of unstructured and structured solvents. The systems water/alcohol/TEOS were effectively characterized as surfactant free microemulsions. The enhanced solvent structuring, however, disappears upon the reaction of TEOS and assembly is directed by solvent structuring found in the binary. For the first time, the influence of solvent composition on the sol-gel reaction was investigated with respect to the reaction rate and the structuring behavior thanks to dynamic light scattering (DLS), small and wide angle X-ray scattering (SWAXS) and transmission electron microscopy (TEM) experiments. The silica nanoparticles aggregate in a different manner depending on the solvent composition, which allow changing the morphology, degree of interconnection and surface area of the resulting material. Silica nanoparticles with very high surface area up to 2000 m²/g can be obtained by this approach.

Introduction

Silica aerogels are industrially widely applied materials¹⁻⁴ due to their unique properties such as low thermal conductivity, low refractive index optical transmission, low density and high specific surface areas⁵. Especially their high porosity and high specific surface area make them a useful choice for many applications like thermal insulation⁶, oil-water separation⁷, analytics⁸ and depollution⁹. Furthermore, their production is nowadays easily scalable. The crucial factor of aerogel synthesis is the conservation of the wet gel structure during drying. To this end, the capillary forces must be minimized by using a low surface tension solvent during drying like supercritical CO₂.¹⁰ To create wet gels that exhibit the desired properties, well-reported templating approaches can be used.¹¹⁻¹⁵ Also, high internal phase emulsions can lead to foams exhibiting interesting properties.¹⁶ Conventionally, large, self-assembling molecules known as surfactants are used because their free energy of structure formation is strongly favorable.¹⁷ However, in a recent study¹⁸, the effect of water/ethanol/dichloromethane microemulsion on the ammonia catalyzed silica polymerization was investigated. They found a connection between the type of microemulsion (W/O, bicontinuous or O/W)¹⁹ and the obtained silica morphology, thus, proving the possibility of templating by surfactant-less microemulsions. In this paper, we investigate the fundamental aspects of using structured solvents in silica aerogel elaboration.

Such structures have been observed in mixtures of small amphiphilic molecules like ethanol (EtOH) or -most prominently- tert-butanol (TBA) and a hydrophilic solvent.²⁰⁻²⁵ The addition of hydrophobic molecules like 1-octanol amplifies this structuring.²⁶⁻²⁹ Here, subtle balances between hydration forces, entropy and curvature play important roles in the solvent structuring on the mesoscale.³⁰⁻³² It is more reasonable to speak of fluctuating hydrophobic and hydrophilic domains instead of defined structures. In spite of their shapeless nature, such compartments show an influence on chemical reactivity.³³⁻³⁶

Among the studies on chemical reactions in such structured solvents, very few deal with the synthesis of polymers³⁷ or the sol-gel process¹⁸. Another recent study³⁸ showed that even the presence of binary mixtures of a deep-eutectic solvent and water is able to influence the silica morphology. A surprising result was reported by Wang et al.³⁹ where a small amount of a co-solvent is responsible for the formation of silica nanosheets.

In this study, the sol-gel process is performed in a system that contains only the essential components: tetraethyl orthosilicate (TEOS) as Si-source, water for hydrolysis, an alcohol to assure solubilization and HCl as catalyst. TEOS content and HCl/TEOS ratio are kept constant, in order to reduce experimental parameters. To investigate the effect of structuring, like mentioned before, TBA is the ideal candidate.²³ For comparison, EtOH was chosen as non-structuring counterpart.

Results and discussion

Phase behavior of the ternary systems

In order to determine the solubility of TEOS in the binary mixtures of alcohol/water and to choose the most suitable sol compositions, first, the phase diagrams of the systems TEOS/alcohol/water were determined. Since TEOS hydrolyzes very fast at low pH, the phase diagram was prepared without catalyst addition. The phase diagrams are presented in **Figure 1**. Sample compositions are also displayed. “A” to “G” denote both A_{C2} and A_{C4} to G_{C2} and G_{C4} . For presentability in **Figure 1**, the water and the HCl weight fraction in the prepared samples (see **Table 2** for compositions) were added to give “ w_{water} ” in the diagram.

Figure 1. Ternary phase diagrams of the systems water/TBA/TEOS (-) and water/EtOH/TEOS (-) in weight fractions determined at $25 \pm 0.5^\circ\text{C}$. The mono- and biphasic regions are indicated in the respective areas. The selected sols are referred A to H (see **Table 2** for compositions). “A” to “G” denote both A_{C2} and A_{C4} to G_{C2} and G_{C4} . For presentability, the water and the HCl

weight fraction in the prepared samples (see **Table 2** for compositions) were added to give “ w_{water} ” in the diagram.

Both phase diagrams show the classical behavior of systems containing two immiscible components, in this case water and TEOS, and a co-solvent, which is completely miscible with the other two. When adding a certain quantity of co-solvent (here: EtOH or TBA) the system can be mixed. The necessary amount to reach the monophasic region depends on the ratio of the immiscible components and the nature of the co-solvent. In addition, for considerations on the solubilization capacity of the co-solvent, a ternary phase diagram in molar fractions is illustrated in the Figure S1 in the Supporting Information. The biphasic area is slightly smaller with TBA than with EtOH. Several reasons for this difference are identified: (i) the nature of the co-solvent, i.e. its polarity or its molecular structure^{17,30,40}, and (ii) the co-solvent-co-solvent and co-solvent-solute interactions.^{29,41} According to earlier work²⁹, the high concentration of a solute with weak co-solvent-solute interactions favors solubilization by the integration of the solute in a hydrophobic pseudophase. In our case, the presence of a sufficient amount of TBA leads to a pre-structuring where the hydrophobic TEOS can be solubilized. In the case of EtOH, this pre-structuring does not exist and the solubilization of strongly hydrophobic compounds is less efficient.

Impact of the TEOS addition to the sol structuring

To gain further information on the samples, their structuring on the mesoscale was investigated by SWAXS. The scattering patterns of the samples without HCl just after the addition of the 7.5 w% TEOS and of their associated binary mixtures are shown in **Figure 2**. The data in **Figure 2 c)** were already published earlier.²⁹ The SAXS spectra of samples F_{CX} to H_{REF} are not displayed in Figure 2 because they are biphasic and, therefore, not comparable to the systems without TEOS. The weight fractions of water of samples A_{CX} were adjusted to

0.1 in binary mixtures and 0.0925 in ternary mixtures to be compared with the data from the literature.

Figure 2. a) and c) SWAXS patterns of binary alcohol/water mixtures. b) and d) SWAXS spectra of ternary TEOS/alcohol/water mixtures at neutral pH just after the 7.5 w% TEOS addition. Data for c) was already published earlier.²⁹ Sample compositions of ternary mixtures are given in **Table 3**.

These SWAXS patterns display several results which depend on the solvent. First, at high q ($q > 3 \text{ nm}^{-1}$) several peaks attributed to the various pair correlations are visible. First, the peak at 20 nm^{-1} assigned to O-O pair correlations in the H-bonding network of water are visible in all patterns. It shifts slightly to smaller q with increasing alcohol contents. This corresponds to an increase of the distances in real space and may indicate the partial disruption of the H-bonded network.⁴² Second, the peaks at 15.5 nm^{-1} for the samples with EtOH and at 13 nm^{-1} for the samples with TBA corresponds to characteristics distances of approximately 0.4 nm and 0.5 nm

respectively and are assigned to the pair correlations between the alkyl chains.⁴³ Whereas their intensity depends on the alcohol content, their position does not shift significantly with the concentrations. The apparent shift of this peak to higher q in EtOH containing samples is due to the superposition with the peak assigned to O-O pair correlations. The apparent broadening upon addition of TEOS is due to the apparition of Si-Si pair correlations at 9 nm^{-1} and 16 nm^{-1} . In these mixtures, the peaks of TEOS are not clearly visible due to its low concentration. Thus, the positions of these peaks were determined using the SWAXS spectrum of pure TEOS. (see Figure S2 in the Supporting Information). Third, the peaks at 8 nm^{-1} (0.8 nm in real space) for EtOH and at 7 nm^{-1} (0.9 nm in real space) for TBA are attributed to the O-O correlation distance of the alcohol $-\text{OH}$ groups.⁴³ Accordingly, the peak intensity decreases with lower alcohol contents.

In the low q region of the pattern ($q < 3 \text{ nm}^{-1}$), significant differences between the two co-solvents can be noticed. In the samples with EtOH, the addition of TEOS, leads to a significant scattering increase presenting various slopes depending on the mixture: For the samples A_{C2} and B_{C2} a constant increase (q^{-1} for A_{C2} to $q^{-2.4}$ for B_{C2}) and no plateau are visible. For sample C_{C2} , D_{C2} and E_{C2} a plateau is reached. The plateau shifts to lower q values with increasing water contents. In the samples with TBA without TEOS, the scattering intensity increases with the water content from $x_{\text{water}} > 0.638$. A plateau is visible that shifts to lower q with increasing water content. After the TEOS addition, this scattering intensity increases noticeably whereas the shape remains the same (around one order of magnitude for sample E_{C4}) and the plateau shifts to lower q .

This intensity increase at low q indicates a structuring at the mesoscale (According to IUPAC 2 to 50 nm).⁴⁴ In the case of EtOH two different behaviors are observed. For lower water content (A_{C2} and B_{C2}), the maximum intensity is not inside the observation window indicating organization on a very large scale. The higher slope for B_{C2} compared to A_{C2} indicates a

structuring change. For C_{C2} and the samples with higher water contents, the intensity limit is in the observed q -range. This may be explained by the formation of large structures with trace amounts of highly hydrophobic compounds.²⁸ In this case, the highly hydrophobic compounds may be the polycondensed oligomers of TEOS which are formed in the commercial product after the first opening due to air humidity.⁴⁵ Thus, the excess scattering at low- q for samples A_{C2} and B_{C2} is assumed to be caused by large shapeless aggregates. When adding more water, these aggregates get increasingly constrained by the H-bonding network of water formed around them (B_{C2}) until reaching objects of less than 30 nm in size (C_{C2} to E_{C2}). In the binary system TBA/water, organization is due to rapidly fluctuating water- or TBA rich aggregates.²⁹ This is typical for short chain alcohol/water mixtures.^{20–24} The visibility of these aggregates on SAXS patterns depends on their size and on their electronic density contrast to the rest of the solution. In EtOH/water mixtures, for example, the aggregates are too small and do not have a sufficiently high contrast to their surroundings to be visible.²² When adding the hydrophobic TEOS a transition to a “pre-Ouzo” system is observed. Depending on the type and the weight percentage of co-solvent this leads to an enhanced structuring.^{29,30,46} In the case of TBA, the preformed structures are swollen by TEOS and this is visible on SAXS pattern by an increase of the intensity and the plateau shift to smaller q . This is due to a higher solubility of TEOS in the TBA-rich domains than in the water-rich domains. Samples which do not present any scattering intensity at low q in the binary mixtures remain unchanged upon addition of TEOS. A size analysis of the aggregates in the structured systems gives insight on its morphology. Characteristic sizes were evaluated by the fitting of SAXS data. Classically, the SAXS patterns of surfactant-free microemulsions can be fitted using then Ornstein-Zernicke (OZ) function. The samples D_{C4} and E_{C4} and their corresponding binary mixtures show good agreement with the fit. In the samples without TEOS correlation lengths of 0.65 nm for the binary mixture corresponding to D_{C4} and 0.77 nm for the binary mixture corresponding to E_{C4} are obtained.

This is in agreement with literature.²⁹ In the samples with TEOS, correlation lengths of 0.88 nm for D_{C4} and 2.82 nm for E_{C4} have been found. Supposing spherical aggregates, the respective aggregate dimensions are 3.52 nm and 11.23 nm. The samples C_{C2} , D_{C2} and E_{C2} are fitted increasingly worse using the OZ function because the slopes at low- q are too steep. However, approximatively, correlation lengths between 1.8 nm (C_{C2}) and 2.5 (E_{C2}) are obtained. The results are in agreement with an O/W microemulsion. The addition of TEOS enhances structuring by (I) swelling the existing structure in the case of TBA or (II) inciting the aggregation of the co-solvent around it in the case of EtOH. When decreasing the alcohol/water ratio (i.e. $D_{C4} \rightarrow E_{C4}$), the system will minimize the interphase formed by the alcohol. This is done by increasing the aggregate size. The results agree with the literature for similar systems. A swollen network of H-bonded groups is probably at the origin of the structuring.⁴⁷ For ternary mixtures with low hydrophobic phase content close to the demixing line, structures resembling O/W aggregates were proposed.⁴⁸

To summarize, ternary mixture TEOS/alcohol/water (where “alcohol” can be EtOH or TBA) are typical surfactant-free microemulsions. The components take their roles as hydrophilic component (water), hydrophobic component (TEOS) and co-solvent or –more generally – hydrotrope (EtOH or TBA). The organization of components at the mesoscale increases when approaching the phase boundary.^{27,49,50} The type and the extend of structuring depends on the co-solvent. When using TBA, the aggregation is heavily influenced by structuring which is already present in the binary mixture TBA/water. They will allow the TEOS solubilization. With EtOH, structures which allow solubilization of TEOS are formed only in the ternary system.^{27,29}

Study of the sol-gel transition

After the addition of HCl used as a catalyzer to initiate the TEOS hydrolysis, the durations before gelification at 50°C were determined by naked eye for both series. To confirm the results obtained by these observations for the TBA series and to reduce the error margins, gel time determination was also performed by DLS. Upon TEOS addition, a slight heating was noticed that indicates the start of hydrolysis. The results are presented in **Figure 3**.

Figure 3. Gel times of the samples as a function of the molar fraction of water x_{water} as determined by observation and by DLS.

Comparing the results obtained by observation and DLS, overall shorter times were observed with the DLS method. However, all trends remain consistent. First, the gel times of the sols with EtOH at $x_{water} < 0.7$ are three times longer than the ones with TBA. This difference is reduced when the water content increases. Second, whatever the solvent, the gel time globally decreases with increasing water content. This evolution follows three stages. Up to $x_{water} = 0.5$, the gel time decreases almost linearly with the water content. For x_{water} higher than 0.5, the gel time decrease follows two different behaviors depending on the solvent. For sols containing EtOH, the gel time decreases linearly from $x_{water} = 0.5$ to $x_{water} = 0.8$ with a lower slope than at lower water contents. For sols containing TBA, the gel time evolution between $x_{water} = 0.5$ and

$x_{water} = 0.8$ presents a minimum for the sample D_{C4} ($x_{water} = 0.677$). Finally, at high water contents ($x_{water} > 0.9$ for TBA and $x_{water} > 0.8$ for EtOH), a strong decrease of gel time is observed. Gel-time depends on the volume fraction occupied by the growing aggregate. Consequently, the aggregate structure has an important influence.

To investigate the morphology of the growing structures with the gel time, the structure evolution was followed by SAXS. The SAXS pattern evolution of the two sols C_{C4} and C_{C2} were chosen to illustrate the behavior and are presented in **Figure 4 a)**.

Figure 4. a) Evolution of the SAXS patterns of the sols C_{C4} and C_{C2} during the sol-gel transition. The symbol color intensifies with sample ageing. b) evolutions of the scattering intensity at $q=0.3 \text{ nm}^{-1}$ of the SAXS patterns as a function of time.

As discussed earlier, immediately after TEOS addition, the observed scattering originates from the mesoscale organization of unreacted components (t_0 in **Figure 4 a)**). During the polymerization, the low q scattering develops the same way for all sols. Three aspects should be highlighted. First, all SAXS patterns present a slope proportional to $\sim q^{-2.1}$ (**Figure 4 a)**). A plateau marks the end of this slope at low q . The evolution rate of this plateau is proportional to the gel time as highlighted by the scattering patterns of C_{C4} 8h and C_{C2} 24h recorded at similar points during the polymerization ($\frac{t}{t_G} \approx 0.12$). During polymerization the plateau shifts to

increasingly low q and higher intensities. Finally, after $\frac{t}{t_G} \approx 0.3$ no plateau is observable. Second, the slope is proportional to $\sim q^{-2.1}$ giving evidence of the nature of polymerization. Third, the initial organization of the water and the alcohol is not visible anymore after TEOS addition probably because its scattering is hidden under that of the developing silica polymer.

The evolution of the low- q scattering pattern is characteristic for objects that primarily increase in size and not in number.¹⁰ Logically, the disappearance of the plateau after $\frac{t}{t_G} \approx 0.3$ indicates that the correlation lengths become too large for the observation window. In **Figure 4 b)**, the scattering intensities of selected samples at $q = 0.3 \text{ nm}^{-1}$ as a function of time are plotted. For all samples, like mentioned before, an increasing intensity is observed at longer times. The intensity increase is accelerated at higher water contents. The acceleration is directly correlated to the gel time of the samples. The shorter the gel times the faster the intensity increases. This is also observed for the development of Si-O-Si bonds as observed in the FTIR spectra (see Figure S3 in the Supporting Information).

The constant slope of $\sim q^{-2.1}$ is characteristic of the formation of fractal objects *via* a reaction limited cluster-cluster growth (RLCA) or a diffusion limited cluster-cluster growth (DLCA).^{10,51,52} Evidence has shown that rearrangements can lead to the same fractal dimensions.⁵³ From the SAXS spectra we conclude that the polymerization rate is proportional to the gel time observed for the sols. Polymerization occurs *via* cluster-cluster aggregation of primary particles that are formed early in the process. The structural evolution is identical for all samples.

With the obtained structural information, the two different behaviors with EtOH and TBA in the region of samples A_{CX} to F_{CX} can be explained by several experimental factors. In order to simplify the explanation, it is assumed that hydrolysis was very advanced in all samples after several minutes and, thus, does not contribute to the gel time. This last assumption is reported in literature^{54,55} and supported by the fact that under acidic conditions, the hydrolysis is

generally faster than condensation and the high $[\text{H}_2\text{O}]/[\text{TEOS}]$ ratio ($[\text{H}_2\text{O}]/[\text{TEOS}] = 15.7$ for samples A_{CX}) increases that effect.¹⁰ This is also visible in the FTIR spectra of all samples which display a peak at 950 cm^{-1} corresponding to the $\equiv\text{Si-O}$ stretching of non-hydrolyzed TEOS only just after the TEOS addition. Moreover, the initially biphasic sample H_{REF} becomes monophasic after 3 min of vortexing due to the increasing hydrophilicity of hydrolyzed species and the production of solubilizing EtOH during the reaction.

The first factor which affects the condensation rate is the concentration of catalytic species. A higher concentration increases the hydrolysis/condensation rate. Here, the catalysis occurs via the protonation of silica species and is proportional to the H_3O^+ concentration.⁵² The qualitative inspection of FTIR spectra (see Figure S4 in the Supporting Information) recorded along the polymerization showed that, indeed, the concentration of H_3O^+ increases with increasing water content. This is accordance with the observed trends.

Second, the re-esterification of hydrolyzed species may also impact the gel time. Indeed, partial re-esterification (RE) of hydrolyzed species is possible due to the reversibility of the hydrolysis reaction and can occur with reactive alkoxy species. RE is also favored under acidic conditions.¹⁰ TBA is too unreactive whereas EtOH is sufficiently reactive for this process to be considered.^{56,57} For our two systems, due to the high concentrations of EtOH compared to the strong dilution of silicate species, it is probable that RE leads to an overall decrease of silicate species reactivity. This effect is more pronounced at higher alcohol concentrations. In mixtures with high water content $x_{\text{water}} > 0.8$ this effect vanishes.

Third, the reaction rate is influenced by the repulsive forces between the charged primary particles and their diffusion. This is described by the aggregation rate constant k , as described in the Supporting Information. The values were calculated from the primary particle radii from the SAXS measurements (Table 1) and the dielectric constants (see Figure S5 in the Supporting Information) and the viscosities (see Figure S6 in the Supporting Information) from literature.

Overall, the estimated reaction rate increases at increasing water concentration (see Figure S7 in the Supporting Information). For one, the viscosity decreases at increasing water concentration. Thus, the diffusion increases and objects potentially encounter each other more frequently. The encounters are moderated by repulsive forces between the objects. The increasing dielectric constant at increasing water concentrations attenuates the repulsive forces and the reaction rate accelerates.

While most of the gel time tendencies can be explained by these factors, the minimum of gel time for the sample D_{C4} cannot be explained by any of the mentioned factors because they describe continuous trends. A hypothesis allowing the explanation of this behavior will be proposed in the discussion part.

Influence of the sol composition on material structure

In order to obtain aerogels, first, a solvent exchange with EtOH was performed to induce the re-esterification of the materials surface making it more hydrophobic.^{58,59} This re-esterification reduces the capillary forces during solvent removal and, thus, minimizes the material modification during drying. Second, another solvent exchange with acetone and SC CO₂ was performed. Acetone was used for its high solubility in SC CO₂. The obtained materials were analyzed by nitrogen adsorption-desorption experiments. The specific surface areas S_{BET} obtained as a function of x_{water} are shown in **Figure 5**.

Figure 5. Specific surface areas (S_{BET}) of aerogels obtained by the BET method as a function of the molar fraction of water x_{water} in the corresponding sol.

Except for the samples D_{C4} and E_{C4} , and whatever the solvent, aerogels have a similar S_{BET} of as around $1000 \text{ m}^2/\text{g}$. For aerogels obtained from sols D_{C4} and E_{C4} S_{BET} of $1400 \text{ m}^2/\text{g}$ and $2100 \text{ m}^2/\text{g}$ are obtained respectively. This result can be related to the particular behavior in the sol-gel process already observed. The solvent of the samples D_{C4} and E_{C4} showed the most pronounced scattering.(see **Figure 2 a**)) Furthermore, the samples D_{C4} and E_{C4} displayed unexpectedly low gel times.(see **Figure 3 a**))

To investigate the morphology at a scale of 1 to 30 nm SAXS was performed (see Figure S8 in the Supporting Information). All samples showed the same scattering intensity evolution characteristic for aerogels produced from one-step acid catalysis.^{60,61} The fractal dimension increases from -2.15 (see **Figure 4 a**)) to values around -2.7 (see Table S1 in the Supporting Information). From this, a typical porosity shrinkage at small size scales can be concluded.^{10,62,63} The radii of the primary particles (r_0) that form the network were determined by fitting the SAXS patterns (see SI for complete results). The results are shown in **Table 1**.

Table 1. The radii (r_0) of primary particles as obtained by fitting the SAXS patterns of the aerogels.

Co-solvent	Reference	r_0 /nm
Ethanol	C_{C2}	0.35 ± 0.04
	D_{C2}	0.30 ± 0.04
	E_{C2}	0.27 ± 0.03
	F_{C2}	0.28 ± 0.03
	G_{C2}	0.29 ± 0.03
<i>Tert</i> -butanol	A_{C4}	0.23 ± 0.03
	B_{C4}	0.32 ± 0.04
	C_{C4}	0.32 ± 0.04
	D_{C4}	0.36 ± 0.04
	E_{C4}	0.28 ± 0.03
	F_{C4}	0.26 ± 0.03
	G_{C4}	0.23 ± 0.03
Ref. without alcohol	H_{REF}	0.27 ± 0.03

The sizes of primary particles can be separated in two domains: In the first, at higher water contents, values between 0.23 and 0.3 nm are obtained. In EtOH containing samples, this is the case at $x_{\text{water}} > 0.58$ (D_{C2}). Whereas in TBA containing samples, this is the case at $x_{\text{water}} > 0.757$ (E_{C4}). In the second, at lower water contents, the particle size evolution depends on the alcohol. In aerogels produced using EtOH as co-solvent, the radii of primary particles decrease continuously until D_{C2} . When using TBA as a co-solvent, r_0 increases up to a maximum at sample D_{C4} . The evolution of the primary particle size when using EtOH as a co-solvent can be explained by the experimental factors mentioned above. Since primary particles are formed in the first instants of the reaction, their size is largely controlled by the hydrolysis reaction. At higher alcohol content, the catalytic activity is lowered. Lower catalytic activity leads to slower hydrolysis. When the hydrolysis is slower, the nucleation is slower and the nuclei formed can grow to larger sizes before the TEOS is completely consumed. At $x_{\text{water}} > 0.58$, the critical size for the nuclei under these conditions is obtained. When using TBA as co-solvent, the water content where the largest primary particles are found (D_{C4}) can be correlated to the structuring in the binary water/TBA system.^{29,34} Here, an inverse structuring with water-rich domains in a TBA-rich phase was proposed. Since the primary particles grow in the aqueous phase, these water-rich domains can serve as microreactors. Inside, the particle growth is controlled by a lower number of nuclei. Containing the same amount of TEOS, this leads to larger particles. When entering the bicontinuous region at higher water contents, a change to nuclei size-limited behavior is observed.

The samples were also characterized by TEM. (**Figure 6**) The enlarged images can be found in the SI.

Figure 6. TEM images of aerogels produced from different sols: a) B_{C2}, b) E_{C2}, c) G_{C2}, d) H_{REF}, e) A_{C4}, f) D_{C4}, g) E_{C4}, h) F_{C4}. Scale bar = 100 nm.

The TEM images show the typical granular structure of aerogels consisting in nanoparticles with radii of 0.2 to 0.8 nm. This agrees well with the sizes obtained by SAXS where radii of 0.23 and 0.36 have been obtained. The structure at the scale of tens of nanometers varies between the samples. Samples where the solvent shows no excess scattering at low q are densely aggregated clusters (see **Figure 6** a) – e) and h). Aerogels that were produced in solvents where excess scattering at low q has been observed show an open network at the mesoscale (see **Figure 6** f) and g)). This coincides with the samples that display increased specific surface areas. It is important to distinguish the porosity observed in samples D_{C4} and E_{C4} from the openings observable in the other samples. In D_{C4} and E_{C4} the surroundings of pores are like elongated bridges and flat surfaces. The openings observed in the other samples show the roughness at the size scale of primary particles and, therefore, merely represent holes due to

sample preparation. Thus, TEM images indicate that the particular behavior observed for the sample D_{C4} and E_{C4} originates from structural differences.

Discussion

Binary mixtures of water and alcohol show interesting properties for the application as solvents in the sol-gel process. In the present comparison of EtOH and TBA, the typical formation of a surfactant-free microemulsion in the ternary mixture of water/alcohol/TEOS was observed. This mesoscale structuring, induced by the addition of hydrophobic TEOS, however, can be considered unimportant for the sol gel process at low pH. The reason is the rapid hydrolysis of TEOS in the examined conditions which leads to the elimination of the hydrophobic compound. Then, the resulting hydrolyzed silicate species react to form sub-nanometer sized primary particles. By further Si-O-Si bond formation between the particles, an open silica network with fractal character is formed. The ratio of water/alcohol or the choice of alcohol does not change the mechanism of polymerization allowing the direct comparison. The network formation proceeds at different rates depending on the water/alcohol ratio which was observed by SAXS, FTIR and gel time measurements. As discussed, several experimental factors are responsible for the different rates. Investigations on the aerogels obtained after drying by SC CO₂, allow the conclusion that, indeed, a network of primary particles was formed during the sol gel process. The aerogels displayed typical properties concerning specific surface areas and SAXS patterns and a typical morphology. However, two samples from the TBA-series display exceptional features that will be discussed in the following. The hypothesis on the mechanism is depicted in **Figure 7** in which the water content increases along the axis. The images illustrate the solvent behavior around the silica polymer. Light blue is water-rich phase, dark blue the hydration layer around silica and green the TBA-rich phase. In the picture illustrating pure water and the mixture 25 w% water in TBA (or TBA in water) the solution is considered as an homogeneous mixture. At the 50/50 mixture the solvent is considered heterogeneous. Here, it creates voids in the silica matrix after the sol-gel process.

Figure 7. Simplified illustration of the structuring at the mesoscale during the sol-gel process according to the proposed mechanism.

Specific case of the C_{C4} and D_{C4} samples: impact of the solvent structuring

All the results obtained for the samples, $n(\text{TBA})/n(\text{water})$ of 0.404 (D_{C4}) and 0.264 (E_{C4}), suggest that compartmentation into water- and TBA-rich domains in mixed solvents is responsible for the gel time and the high specific surface area through the modification of the immediate environment of the growing silica polymer. Those ratios $n(\text{TBA})/n(\text{water})$ are similar to the ratios in the TBA/water binary mixtures for which structuring has been observed.^{25,34} However, this structuring is different from the effect of structuring due to the templating formed by the aggregation of large amphiphilic molecules. The free energy gain of structure formation in the binary mixtures is very little. Therefore, the introduction of highly hydrophilic silica will influence the morphology of separated TBA-rich and water-rich domains

instead of forming silica around existing domains. In this case, water-rich domains cover the surface of the growing silica polymer while TBA-rich domains are not in contact with silica. (see **Figure 7**) The reason is the positive surface charge on the silica surface that exists at the high acid concentrations ($\approx 1\text{mol/L}$) in our experiments⁶⁴. The resulting counter-ion layer of solvated chloride ions supports the hydrophilicity. Thus, the immediate environment of the silica polymer can be considered as a bulk water phase above $x_{\text{water}} \approx 0.5$. As visible by the highest reaction rate observed for H_{REF} , a solution containing more water has an accelerating effect. The accelerating effect is most pronounced at sample D_{C4} because the catalyst concentration in the water-rich domain is the highest. When adding more water, the catalyst in the water-rich domain gets diluted. This modification of the immediate environment appears to have an important effect on the specific surface area. The TBA-rich domains, although strongly fluctuating, are volumes that are excluded for the growing silica polymer. The excluded volumes will lead to pores in the aerogel (see **Figure 7**) which ultimately lead to unique structural features like observed in the TEM images. The size discrepancy between the solvent structuring in the binary case water/TBA and the observed morphological features is well documented in literature.^{65,66} These excluded volume pores connect the typical microporosity. In the case of unstructured solvents, the microporosity is inaccessible to N_2 for measurement. When mesoscale structuring is present, however, microporosity is accessible and leads to a significant increase of specific surface area.

Conclusion

In this work, the influence of a structured solvent on the kinetics and the resulting morphology of the sol-gel process was investigated. The results are promising for applications in several domains where high specific surface areas are important.^{6,7,67,68} For the investigation, binary mixtures of water/EtOH and water/*tert*-butanol were chosen as representatives of unstructured (EtOH containing) and structured (*tert*-butanol containing) solvents. Upon the addition of

hydrophobic TEOS, enhanced structuring was observed for several samples, which agrees with literature.²⁹ After the rapid hydrolysis of TEOS (< 3 min) which was at the origin of the enhanced solvent structuration the solvents are assumed to return to their state in the binary mixtures. Here, the reaction conditions and structuring on the mesoscale determine the size of primary particles. Small silica particles (radii between 0.2 and 0.5 nm^o) then react with each other to form a fractal network. Discontinuity of the reaction rate between the samples was observed in sols containing the structured solvent (*tert*-butanol) by observation, DLS, FTIR and SAXS. Furthermore, the aerogels obtained by drying with SC CO₂ display noticeable morphological features and specific surface areas when resulting from structured solvents. These criteria lead to the conclusion that the solvent structuring in the immediate environment of the silica particles is responsible for the behavior observed. A hypothesis of the influence of the solvent structuring on the polymerization mechanism is proposed where the silica particles aggregate in a different manner depending on the solvent composition in their close surrounding. In structured solvents water-rich domains cover the silica particles. This leads to reaction conditions that are similar to those in pure water while *tert*-butanol-rich domains form regions where polymerization does not take place.

Experimental

Chemicals

Ethanol absolute anhydrous (p.a.), acetone (technical grade) and 37 w% HCL solution (p.a.) were purchased from Carlo Erba Reagents (Val de Reuil, France). *Tert*-butanol (p.a., $\geq 98\%$) was purchased from Sigma-Aldrich (Darmstadt, Germany). Tetraethyl orthosilicate (TEOS) ($\geq 98\%$) was purchased from Acros Organics (Geel, Belgium). Chemicals were used without further purification. Aqueous solutions were prepared using Milli-Q water.

Ternary phase diagrams

Ternary phase diagrams were determined at room temperature using a static and dynamic process as described in literature.²⁹ For this purpose, binary mixtures of water/alcohol and alcohol/TEOS were prepared. The third component was added dropwise and the tube was stirred after every addition. The composition at the moment of demixing was noted as the phase boundary. After every addition, the tube was closed and then stirred. To limit the TEOS hydrolysis, ultrapure water was used.

Material preparation

From the ternary diagrams, several water/alcohol ratios were selected and are referred A_{cx} to G_{cx} with $X=2$ for ethanol and $X=4$ for *tert*-butanol (*Table 2*). For the sample H_{REF} no alcohol was added. The materials were prepared using an acid catalyzed sol-gel process. Ethanol or TBA, water and 37 w% HCl were mixed in the appropriate ratios indicated in *Table 2*. After stirring, TEOS was added and the container was closed. . Biphasic samples were vortexed until complete mixing. The longest time required to obtain a monophasic sample was 3 min for H_{REF} (*Table 2*). Afterwards, the sols were kept in an oven at 50°C until two days after gelification. Then, the gels were transferred into 100 mL of ethanol and aged for one day at room temperature. Next, ethanol was decanted from the transparent gels and 100 mL of acetone were added. After ageing for 24h, the decanted gels were dried using supercritical (SC) CO₂ process.

This was performed with a SEPAREX supercritical fluid extractor using a SC CO₂ flow of 30 g/min, at 100 bar and 60°C during 3 hours. The obtained white powders were kept in the glove box to prevent degradation. The sample references and compositions are presented in the *Table 2*.

Table 2. References, weight and molar fractions of alcohol and water in the samples containing 7.5 w% TEOS and 3.6 w% HCl ($n(\text{TEOS})/n(\text{HCl}) = 2.78$). Their localization in a ternary phase diagram is shown in **Figure 1**.

Co-solvent	Reference	Weight fractions		Molar fractions

Characterization techniques

Gel times were determined by the naked eye and using dynamic light scattering (DLS) at 50°C on a Zetasizer Nano ZS (Malvern Panalytical Ltd., United Kingdom) with automatic attenuation in silicone glue sealed 10 mm polystyrene cuvettes. Acquisition was performed at 173° for 5 runs of 20 s each every hour and data were treated using a method adapted from literature.⁶⁹ The time of the last correlation function consisting of a single monomodal exponential function was chosen as gel-time.

Sols were analyzed using Fourier Transformed Infrared spectroscopy (FTIR) with a Perkin Elmer Spectrum 100 spectrometer in Attenuated Total Reflection (ATR) mode equipped with a DTGS/KBR detector. The samples were placed at the surface of the diamond in a PTFE set-up to avoid solvent evaporation. The spectra were recorded from 380 to 4000 cm^{-1} adding 4

scans with a 4 cm^{-1} of resolution correcting from the background spectrum for each substrate. Baseline adjustments and peak decomposition were performed using the Origin software.

Small and Wide Angle X-ray Scattering (SWAXS) analysis were carried out in transmission geometry with a Xenocs setup equipped with a Mo anode ($\lambda = 0.71\text{ \AA}$) using a MAR345 2D imaging plate detector. Such short wavelength allows to cover a scattering range for standard SWAXS that extends to large wave vectors in order to obtain information at a small scale down to few angstroms typically a wavenumber q ranged from 0.2 nm^{-1} to 30 nm^{-1} . The collimation was ensured by a Fox2D multilayer mirror and by a set of scatterless slits that delimited the beam to a square section (0.8 mm side length at the sample position). The distance from the sample to the detector was about 750 mm and was calibrated using silver behenate powder. Sols were analyzed in glass capillaries of 2 mm of diameter. Azimuthal averaging of 2D-data recorded by a MAR345 imaging plate detector was performed using the FIT2D software taking into account the electronic background of the detector, the empty cell subtraction and an intensity calibration. The scattered intensity in absolute scale (in cm^{-1}) was expressed versus the magnitude of the scattering vector $q = (4\pi\sin\theta)/\lambda$, where θ was the scattering angle. Experimental resolution was $\Delta q/q = 0.02$. Data was fitted using the SASfit software.

Nitrogen adsorption-desorption analyses were carried out using a Micromeritics apparatus (ASAP 2020). Before analysis, all samples were outgassed at $60\text{ }^{\circ}\text{C}$ during 24 h under high vacuum (10^{-5} Pa). Specific surface area was obtained using the Brunauer–Emmett–Teller (BET) model.

For transmission electron microscopy (TEM) and high-resolution transmission electron microscopy (HRTEM) measurement, one or more drops of the dilute solution of dried aerogels in ethanol are deposited on the amorphous carbon film. High-resolution transmission electron microscopic measurements were carried out using a JEOL 2200FS microscope that operates at

200 kV. Transmission electron microscopy observations were then carried out using a FEI Tecnai G2 TEM microscope equipped with a LaB6 filament that operates at 200 kV.
