Seismic anisotropy

ABSTRACT

We studied a suite of mantle xenoliths carried by Cenozoic volcanism in the Borborema Province, NE Brazil. These xenoliths sample a subcontinental lithospheric mantle affected by multiple continental convergence and rifting events since the Archean. Equilibrium temperatures indicate a rather hot geotherm, implying a ca. 80 km thick lithosphere. Most xenoliths have coarse-granular and coarse-porphyroclastic microstructures, recording variable degrees of annealing following deformation. The high annealing degree and equilibrated pyroxene shapes in coarse-granular peridotites equilibrated at ~900 °C indicate that the last deformation event that affected these peridotites is several hundreds of Ma old. Coarse-porphyroclastic peridotites equilibrated at 950–1100 °C probably record younger (Cretaceous?) deformation in the deep lithospheric mantle. In addition, a few xenoliths show fine-porphyroclastic microstructures and equilibrium temperatures ≥ 1200 °C, which imply recent deformation, probably related to the dykes that fed the Cenozoic volcanism. Chemical and microstructural evidence for reactive percolation of melts is widespread. Variation in textural and chemical equilibrium among samples implies multiple melt percolation events well spaced in time (from Neoproterozoic or older to Cenozoic). Crystal preferred orientations of olivine and pyroxenes point to deformation controlled by dislocation creep with dominant activation of the [100](010) and [001]{0kl} slip systems in olivine and pyroxenes, respectively, for all microstructures. Comparison of xenoliths' seismic properties to SKS splitting data in the nearby RCBR station together with the equilibrated microstructures in the low-temperature xenoliths point to coupled crust-mantle deformation in the Neoproterozoic (Brasiliano) continental-scale shear zones, which is still preserved in the shallow lithospheric mantle. This implies limited reworking of the lithospheric mantle in response to extension during the opening of the Equatorial Atlantic in the Cretaceous, which in the present sampling is restricted to the base of the lithosphere.

1. Introduction

Continental plates have long-lived histories. They are usually composed by crustal domains with varied tectonic ages and tectonic reworking is a common feature in crustal exposures. Yet, major tectonic events such as convergence, collision, and rifting involve the entire plate, not only the crust. By consequence, large volumes of the subcontinental lithospheric mantle must have been affected by a succession of tectono-thermal events (cf. reviews in Tommasi and Vauchez, 2015; Vauchez et al., 2012). In addition, during orogenic events, the strain regime frequently changes across the belt, with contiguous crustal domains recording transcurrent motions and thrusting for instance.

However, the level of coupling between crust and mantle deformations during major tectonic episodes is still matter of debate.

Comparison between SKS splitting data and crustal structures points to coherent kinematics, implying at least partial coupling between the crust and the mantle in many orogenic belts (Tikoff et al., 2004). As recognized since the early times of seismic anisotropy measurements (e.g., Vauchez and Nicolas, 1991), crust-mantle coupling is well documented beneath large-scale strike slip faults and transpressional belts, such as the San Andreas fault (Bonnin et al., 2012) or the Pyrenees, the Appalachians, and the neoproterozoic Ribeira-Aracuai belt of SE Brazil (cf. review in Vauchez et al., 2012). In contrast, in collisional domains submitted to large amounts of thickening, like the Alps and the

Southern Tibet, or in active continental rifts, such as the East African rift system, polarization directions of fast split SKS or SKKS waves are usually parallel to the trend of the belts or rifts, but at high angle to the lineations marking flow directions in the ductile crust and to the slip directions in active faults (e.g., Barruol et al., 2011; Wu et al., 2015; Hammond et al., 2014). This suggests at least partial decoupling between the crust and lithospheric mantle (Tommasi et al., 1999).

However, seismic anisotropy data only offer indirect information on the present-day structure of the upper mantle. Moreover, unless a variety of methods based on waves with different incidence angles and propagation directions are employed, localizing vertically the source of the anisotropy remains difficult. Analysis of mantle xenoliths, which are mantle fragments carried to the surface by volcanic episodes, allows for direct sampling of the lithospheric mantle. This sampling is imperfect: it is discontinuous, non-oriented, and focused along the magmatic conduits. Nevertheless, the characterization of the xenoliths' microstructures and associated crystal preferred orientations, as well as of their chemical compositions and mineralogy, allows determining the relative deformation, annealing, and petrological (partial melting, reactive melt transport, solid-state reequilibration) history, even if no absolute dating is possible. Coupling petrophysical analyses on mantle xenoliths to seismological data may therefore allow constraining the deformation history of the lithospheric mantle and hence discussing crust-mantle coupling during major tectonic events.

In this article, we present a petrostructural study of peridotite xenoliths entrained by Cenozoic volcanism in NE Brazil. Based on these data and on published SKS splitting measurements (Assumpção et al., 2011; Bastow et al., 2015), we try to unravel the tectono-thermal evolution of the continental lithospheric mantle in this region, which has been affected by multiple collisional and extensional episodes since the Archean. Analysis of the presently outcropping crustal structures highlights a series of tectono-magmatic episodes, among which the most important and recent ones are: (i) extensive intraplate deformation in a convergent setting, which produced a continental-scale system of strike-slip shear zones and transpressional belts accommodating lateral escape of this domain during the formation of the Gondwana and (ii) extension, localized in a series of intracontinental basins, during the early stages of the opening of the Equatorial Atlantic.

2. Geological and geophysical background

2.1. Evolution of the Northern Borborema Province (NBP)

The analysis of the crustal rocks outcropping in the Northern Borborema Province (NBP) points to a complex tectonic evolution, which probably started in the Archean, as indicated by U-Pb ages ranging from 3.4 to 2.7 Ga recorded in the São José Massif (Souza et al., 2016), ca. 100 km to the east of the study area, and in smaller nuclei elsewhere in the province. Between 2.1 and 2.4 Ga, a major crust formation event produced ca. 50% of the present-day outcropping rocks (Hollanda et al., 2011; Souza et al., 2016). The tectonic setting for this extensive magmatic activity is discussed, but isotopic data indicates significant recycling of pre-existing crustal material (Hollanda et al., 2011).

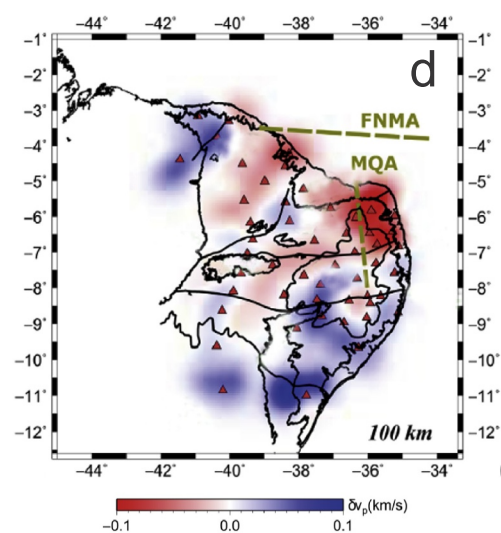

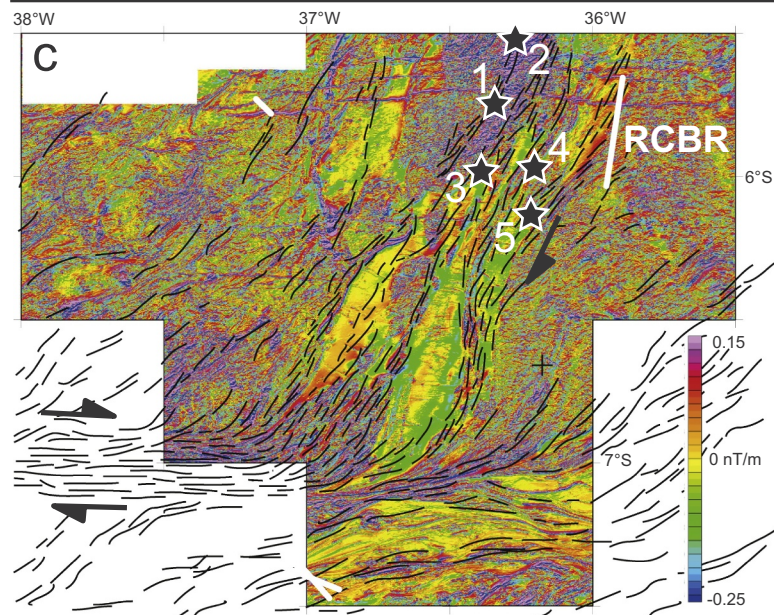

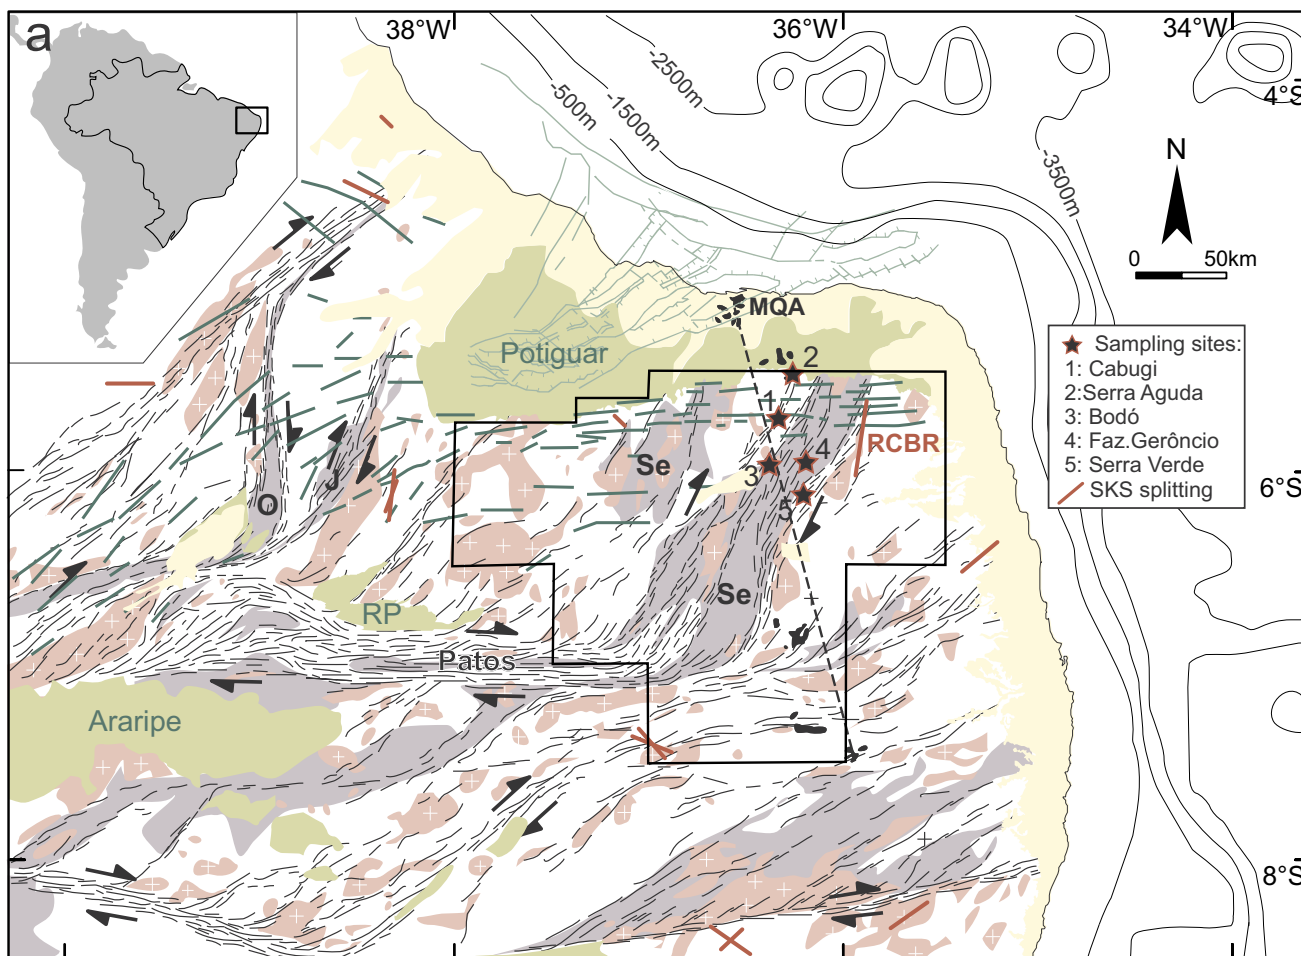

The Meso- to Neoproterozoic evolution of the Borborema Province is characterized by a series of failed intracontinental rifting episodes. At 1.8–1.9 Ga, the Orós and Jaguaribe volcano-sedimentary basins formed to the west of the study area (Fig. 1). This localized extension was accompanied by intrusion of small volumes of alkaline granites and orthosites elsewhere in the province, which lasted until 1.75 Ga (Sa et al., 1995; Hollanda et al., 2011). At 1–0.9 Ga, extension affected the central Borborema Province (Santos et al., 2010; van Schmus et al., 2008). A last extensional episode in the Neoproterozoic affected most of the province. I, formed the Seridó basin within the study area (Fig. 1). The youngest sedimentation in this basin occurred at ~630–615 Ma, but early sedimentation may be as old as 1.8 Ga (Hollanda et al., 2015),

suggesting an early rifting episode simultaneous with the formation of the Orós and Jaguaribe basins.

The major tectono-magmatic episode that affected the Borborema Province, shaping its present-day geology, is, however, the compressional Brasiliano event between 595 and 540 Ma (e.g., Neves, 2003; Archanjo et al., 2008, 2013; Viegas et al., 2014). This event resulted in extensive tectono-thermal reworking of the province through the formation of a continental-scale transcurrent shear zone system (the Borborema shear zone system, Vauchez et al., 1995), transpressional inversion of the Proterozoic metasedimentary basins, and widespread emplacement of granitoids (Fig. 1). The granitoids geochemistry indicates a dominant component of crustal reworking (Neves, 2003; Souza et al., 2016), implying an intraplate setting for the Brasiliano deformation, with a possible convergent plate boundary > 500 km to the NW from the study area (e.g., Caby et al., 1991; Ancelmi et al., 2015). The complex network of anastomosing E-W and NE-SW trending ductile dextral strike-slip shear zones, some up to 25 km wide, and transpressional belts deformed under high temperature, low pressure conditions, which compose the Borborema shear zone system, is therefore the expression of strain localization in an intraplate setting controlled by large-scale intraplate rheological heterogeneities (the basins) in response to the convergence between São Francisco, Amazonian, and West African cratons during the construction of the Gondwana (Tommasi et al., 1995). This shear zone system allowed for tectonic extrusion of the Borborema Province towards the NE (Ganade de Araujo et al., 2014, 2016), that is, towards the Saharan province, which, like the Borborema, had been weakened by tectono-magmatic activity during the Meso- and Neoproterozoic.

In the early Cretaceous, the Borborema province experienced regional extension before rifting localized at the present location of the equatorial Atlantic Ocean (Darros de Matos, 1999). Structures associated with these early stages of rifting in the northern Borborema Province include several intracontinental basins or aborted rifts and a large tholeiitic dyke swarm. The basins formed as NW-SE trending asymmetric grabens (e.g., Potiguar, Rio do Peixe, Araripe in Fig. 1) controlled by reactivation of the Brasiliano shear zones (Darros de Matos, 1999; Castro et al., 2007, 2012; Marques et al., 2014). They contain dominantly continental sediments of fluvial and lacustrine origin, which attain thicknesses of 2000 m, deposited between 145 and 125 Ma. The Potiguar basin is the best developed among these basins; its offshore domain is the only one involved in the final opening of the Atlantic. The Ceará-Mirim dyke swarm is a > 350-km-long tholeiitic dyke swarm with a dominantly E-W trend that rotates to NE-SW at the southern termination of the Potiguar basin (Fig. 1). The dykes have ages between 135 Ma and 120 Ma (Hollanda et al., 2018 and references therein). Their emplacement is therefore synchronous to the formation of the intracontinental basins. Geochemical data points to primary magmas formed by melting of an enriched mantle ($EMI \pm FOZO$ isotopic signatures) at shallow depths (< 90 km; Ngonge et al., 2016a).

The Cenozoic is characterized by a long-lived, but small-volume alkaline volcanism (both onshore and offshore), tectonic inversion of the Mesozoic intracontinental basins, and uplift of the Borborema Plateau. The entire Borborema Province sits nowadays on average at ~800 m above the sea level and the Araripe basin is topographically > 500 m above the Precambrian basement. Analysis of river profiles implies that most uplift occurred within the last 30 Ma (Tribaldos et al., 2017), but earlier events may have occurred (Marques et al., 2014; Nogueira et al., 2015). The present day crustal thickness of 30–35 km implies some degree of sub-lithospheric support for the uplift. The offshore Cenozoic volcanism forms an E-W volcanic alignment that extends from the Ceará coast in northeast Brazil (the Mecejana volcanic field) to the Fernando de Noronha archipelago. The Mecejana volcanics yield K-Ar ages between 26 and 44 Ma (Mizusaki et al., 2002), whereas volcanism in Fernando de Noronha has Ar-Ar ages between 12.5 and 6 Ma (Perlingeiro et al., 2013). The onshore Cenozoic volcanism is distributed along a N-S trend, forming the Macau-Queimadas

(caption on next page)

Alignment (MQA, Fig. 1). Emplacement ages range between 52 Ma and 7 Ma, with two peaks around 26–29 Ma and 7–9 Ma and no clear age progression along the MQA (Souza et al., 2003; Silveira, 2006; Knesel et al., 2011).

The Macau volcanics that entrained the studied mantle xenoliths (Fig. 1) erupted onto metasediments from the Neoproterozoic Seridó belt or Mesoproterozoic gneisses that form their basement. In the study area, the Brasiliano event is recorded by multiple NE-SW shear zones, which branch off from the E-W Patos shear zone in the south, by transpressional structures in the Seridó belt, and by intrusion of granitoids. The Cretaceous Ceará-Mirim dyke swarm crosscuts the study area with an E-W trend and the Potiguar basin outcrops north of it (Fig. 1).

2.2. Geophysical data

P-wave receiver functions, deep seismic refraction experiments, and surface-wave dispersion data indicate that the crust thickness varies from 30–32 km in the northern Borborema Province to 36–38 km in the southern part of the province (Oliveira and Medeiros, 2012; Almeida et al., 2015; Lima et al., 2015; Luz et al., 2015). This variation in crustal thickness is consistent with gravity data (Oliveira and Medeiros, 2018) and correlated with topography: elevated regions show thicker crust. Receiver function data also imply an intra-crustal discontinuity at 9–18 depth, most often observed in domains with thinner crust, such as the area sampled by the studied xenoliths (Almeida et al., 2015).

Gravity and magnetic data illuminate the structuration of the deep crust in the Borborema province (Oliveira and Medeiros, 2018). These data establish the Patos, Pernambuco, and Jaguaribe shear zones as major structures, which splay off from the Transbrasiliano Lineament, separating four crustal blocks with different geophysical characteristics: the Southern, the Transversal, the Ceará, and the Rio Grande do Norte domains. The studied xenoliths sample the mantle beneath the Rio Grande do Norte domain, which is delimited by the Jaguaribe and Patos shear zones to the west and south, and by the Atlantic Ocean to the north and east. This domain is characterized by strong magnetic contrasts with E-W or NNE trends, correlated with the outcropping Brasiliano structures (Fig. 1c). Magnetic anomalies also clearly define the Ceará-Mirim dykes (Fig. 1c). In addition, analysis of the Bouguer gravity anomaly shows that most of the Rio Grande do Norte domain is characterized by weak long wavelength positive anomalies, which follow the trend of the coastline (cf. Fig. 7 of Oliveira and Medeiros, 2018), suggesting that crustal thinning related to the Atlantic opening affected most of the domain.

The first kilometers of the lithospheric mantle structure may be probed by the analysis of Pn velocities, which decrease from 8.1 km/s to 7.9 km/s in a NW-SE refraction profile across the Borborema Province to the south of the study area (Lima et al., 2015). In the vicinity of the study area, Pn velocities are ~8.0 km/s, which for an isotropic mantle with a spinel-lherzolite composition would correspond to sub-Moho temperatures of 700–750 °C (Schutt et al., 2018).

No seismic velocity data is available for the deeper sections of the lithospheric mantle, but a recent P-wave regional travel-time tomography model (Simões Neto et al., 2019) imaged slower than average velocities at depths < 150 km in the northeastern Borborema province, just east of the study area (Fig. 1d). This low velocity anomaly coincides with a local geoid anomaly of +10 m (Ussami et al., 1999). Slower than average P-wave velocities in the shallow mantle beneath the study area are coherent with a rather shallow Lithosphere Asthenosphere

boundary (LAB), estimated at 80 km depth based on S receiver function data from the station RCBR (Heit et al., 2007). The results of the regional P-wave tomography for the northeastern Borborema Province are also consistent with global finite-frequency tomography models, which image lower than average S-wave velocities in the mantle at 250-km depth in this region (French et al., 2013).

SKS splitting data in the Borborema Province (Bastow et al., 2015) show a complex pattern, with highly variable delay times and fast polarization directions, which in some places closely follow the Neoproterozoic crustal fabric, but are oblique to it in others (Fig. 1a, c). The station closest to the xenolith sampling sites - RCBR (Fig. 1a, c) - shows a NNE-oriented fast S-wave polarization subparallel to the Brasiliano transpressive structures in the northern Seridó belt and its gneissic basement and a high delay time (1.9 ± 0.2 s) based on 9 individual measurements (Assumpção et al., 2011).

2.3. Previous studies of Macau peridotite xenoliths

The petrology and the geochemistry of Macau mantle xenoliths were studied by Comin-Chiaramonti et al. (1986), Princivalle et al. (1994), Fodor et al. (2002), Rivalenti et al. (2000, 2007). These studies identified two microstructural groups: protogranular (the dominant type) and (rare) porphyroclastic (partially recrystallized) peridotites. Protogranular microstructures are mainly observed in lherzolites, whereas porphyroclastic microstructures are usually observed in harzburgites. Protogranular peridotites also yield lower two-pyroxene equilibrium temperatures (825 ± 116 °C) than porphyroclastic ones (> 1150 °C). Trace-element patterns and isotopic compositions of the peridotites indicate variable degrees of metasomatism by alkali-basaltic melts with EMI and minor EMII isotopic signatures, probably during multiple metasomatic events (Rivalenti et al., 2000, 2007).

3. Methods

3.1. Sampling

We have studied 22 xenoliths from 5 different Macau volcanic sites, which extend in a rough N-S trend, from the limit of the Potiguar basin to ~70 km south of it (Fig. 1). Most xenoliths analyzed in the present study come from the Pico do Cabugi basaltic neck ($5^{\circ}42.3'S$, $36^{\circ}19.4'W$). The Pico do Cabugi basalts yield Ar-Ar ages 24.6 ± 0.8 Ma (Souza et al., 2003 and references therein). Among the 16 xenoliths of the Pico do Cabugi in this study, 14 (marked as CA) have been collected by the authors in a field campaign in 2016 and two (marked as PC) were previously studied by Rivalenti et al. (2000).

We also analyzed 6 xenoliths previously studied by Rivalenti et al. (2007): two from the Serra Aguda neck (AG, $5^{\circ}31'S$, $36^{\circ}17'W$), ~30 km north of the Pico do Cabugi, at the border of the Potiguar basin (Fig. 1), one from the Serra Preta do Bodó dykes (BO, $5^{\circ}58'S$, $36^{\circ}22'W$), ~20 km south of Pico do Cabugi, and four from Fazenda Geroncio (GR, $5^{\circ}58'S$, $36^{\circ}14'W$) and Serra Verde localities (SV, $6^{\circ}06'S$, $36^{\circ}12'W$), located ~30 and ~50 km south of Pico do Cabugi (Fig. 1). There are no ages for the Fazenda Geroncio and Serra Verde volcanics, but the Serra Aguda basalts were dated at 26 Ma (Silveira, 2006) and those at Serra Preta do Bodó, at 7.1 Ma (Knesel et al., 2011).

Most xenoliths are small (on average 3 cm of diameter), but they are very fresh. The samples display no macroscopic evidence for major interaction with the host lava. However, small pockets and films of fine-grained clinopyroxene, spinel, and olivine along grain boundaries were

Fig. 2. Microstructural parameters calculated from EBSD data: (a) Olivine shape factor vs. intragranular misorientation relative to the mean orientation of the grain (M2M); (b) Orthopyroxene shape factor vs. olivine M2M. All quantities are average values at the sample scale weighted by the grains' area (cf. Table 2). Similar data for Fernando de Noronha (FN) xenoliths, which sample an old domain of the equatorial Atlantic (Liu et al., 2019), are presented for comparison.

observed under the microscope, in particular close to the borders, in many samples. In addition, some xenoliths have pyroxenes with spongy borders, indicative of limited partial melting during extraction. These domains were carefully avoided during microprobe analyses. They were sometimes included in the EBSD analyses, but affect weakly the results because of their small area.

3.2. Electron-backscattered diffraction (EBSD) data acquisition and treatment

Petrostructural analyses were performed on all samples. Crystallographic preferred orientations (CPOs) of olivine, pyroxenes, and spinel were measured by indexing of electron-backscattered diffraction patterns in the SEM-EBSD facility at Geosciences Montpellier, France. Data acquisition was performed using a JEOL JSM 5600 scanning electron microscope with 17 kV acceleration voltage and 24 mm

working distance. We performed EBSD mapping over the entire thin section (areas $\geq 2 \times 3 \text{ cm}^2$) with step sizes between 14 μm and 35 μm , depending on grain size. Indexation rates varied between 84% and 97%. Non-indexed points correspond mainly to fractures. During post-acquisition data treatment, we eliminated inaccurate indexing points ($\text{MAD} > 1.3^\circ$ and wild spikes), corrected for rare olivine pseudo-symmetry misindexing, and filled up non-indexed pixels with at least 6 coherent neighboring measurements with the average of the neighbors' orientations.

The CPO data analysis, that is, the calculation of the orientation distribution functions (ODF) and of the misorientations, the computation of the strength and symmetry of the olivine CPO, the plotting of pole figures, and the quantification of the microstructure (grains' size, shape, and orientation), was performed using the MTEX toolbox in Matlab (<http://mtextoolbox.github.io/>; Hielscher and Schaeben, 2008; Bachmann et al., 2010; Bachmann et al., 2011). The ODFs were

(b, d, f, g) EBSD phase maps, which better illustrate the variation in shape of olivine and pyroxenes between the three microstructures. (g) Detail of a partially recrystallized domain in fine-porphroclastic lherzolite AG6 indicated by the white square in (f). (h) Misorientation relative to the mean orientation of the grain (M2M) map illustrating the difference in intragranular misorientation in olivine between porphyroclasts (high M2M) and neoblasts (low M2M) in the same domain.

calculated using a “de la Vallée Poussin” kernel function with a half-width of 10° . The CPO is presented as one crystallographic orientation per pixel in pole figures (lower hemispheric stereographic projections). Thin sections were cut in random orientations, because of the small size of the xenoliths. To facilitate comparison between samples, we rotated the CPO of all samples into a common reference frame, in which the maximum concentration of [100] of olivine is parallel to the E-W direction and the maximum concentration of [010] axis of olivine is parallel to the N-S direction of the pole figure. The choice of this reference frame can be justified a-posteriori by the analysis of the CPO, which indicates that this reference frame probably corresponds to the lineation and normal to the foliation directions (cf. Discussion).

The strength of the CPO was quantified using the dimensionless J-index (Bunge, 1982). The J-index for a random CPO is 1; it can reach up to 20 in natural peridotites, with a peak at 3–5 (Tommasi and Vauchez, 2015). We use the dimensionless BA-index, based on the eigenvalues of the [100] and [010] axes orientation distributions (Mainprice et al., 2014), to characterize the olivine CPO symmetry. This index allows classifying the olivine CPO into three types: (i) fiber-[010], characterized by a [010] point maxima and girdle distributions of [100] and [001] (BA-index < 0.35), (ii) orthorhombic, characterized by point maxima of [100], [010], and [001] ($0.35 < \text{BA-index} < 0.65$) and (iii) fiber-[100], characterized by a point maxima of [010] and girdle distributions of [010] and [001] (BA-index > 0.65). J- and BA-indexes do not depend on the reference frame.

To analyze quantitatively the microstructure, we used the grain detection method in MTEX (Bachmann et al., 2011) defining grains boundaries by misorientation angles between adjacent pixels higher than 15° . Grains composed by < 10 pixels were not considered in the microstructural analysis. The misorientation of each pixel relative to the mean orientation of the grain (M2M) and the grain orientation spread (GOS) were calculated to quantify the intracrystalline orientation gradients, which are a proxy for the dislocation density. In addition, we characterized the sinuosity of the grain boundaries by the shape factor, which is the ratio of the perimeter of the grain over the perimeter of a circle with the same area. Both the intra-granular

misorientation (M2M and GOS) and the sinuosity of grain boundaries (shape factor) should decrease in response to recrystallization.

3.3. Mineral compositions and equilibrium temperatures

Mineral compositions of olivine, orthopyroxene, clinopyroxene, and spinel were analyzed in ten samples, selected based on their microstructure, so that all microstructural types were represented. Measurements were performed in a Cameca SX100 electron microprobe at the Microsonde Sud facility at the University of Montpellier, France at a 20 kV accelerating voltage and a 10 nA current. For each sample, we analyzed both rim and core composition in 3 to 4 grains for olivine, orthopyroxene, clinopyroxene, and spinel.

We calculated equilibrium temperatures based on the clinopyroxene-orthopyroxene geothermometer (Taylor, 1998) and on the Ca-in-opx geothermometer (Brey and Kohler, 1990; revised by Nimis and Grutter, 2010). Average rim and core equilibrium temperatures were calculated by averaging the temperatures calculated using 3–4 rim or core compositions of individual opx grains or opx-cpx pairs for each sample. Since no reliable barometers are available for spinel-facies peridotites, we chose arbitrarily 1.5 GPa (~ 46 km depth) as the pressure to calculate the two thermometers. Changes in the assumed pressure produce a variation of $\sim 10^\circ\text{C}$ per 0.5 GPa (~ 11 km).

3.4. Seismic properties

Seismic properties of each sample were computed using the MTEX toolbox (Mainprice et al., 2011), using Voigt-Reuss-Hill averaging based on the CPOs and modal content of olivine, orthopyroxene, and clinopyroxene derived from the EBSD maps and on the single crystal elastic constant tensors of the three minerals and their temperature and pressure derivatives (Abramson et al., 1997; Anderson et al., 1992; Chai et al., 1997; Isaak et al., 2006; Jackson et al., 2007; Sang and Bass, 2014). Average seismic properties for the lithospheric mantle beneath the study area were estimated by averaging the elastic constant tensors of all samples with all CPO data rotated into a common reference frame.

Table 2
Quantitative texture and microstructure parameters derived from EBSD mapping for olivine, orthopyroxene, and clinopyroxene.

Sample	Microstructure/domain analyzed		Olivine							Orthopyroxene			Clinopyroxene	
			J-index	BA-index	M2M (°)	GOS (°)	Shape factor ^a	Grain size ^a (μm)	Aspect ratio ^a	Shape factor ^a	Grain size ^a (μm)	Aspect ratio ^a	Grain size ^a (μm)	Aspect ratio ^a

All values are averages over the entire EBSD map, weighted by the grain area.

M2M: misorientation relative to mean orientation of the grain; GOS: grain orientation spread; Rex: recrystallized.

^a Grain sizes, aspect ratios, and shape factors are apparent 2D values. Aspect ratios may be underestimated since many sections were not cut on the XY structural plane.

^b J-index values that are probably overestimated due to the small number of coarse grains in the thin section (small samples).

The assumption is that the orientation of the lineation and foliation is constant both laterally and vertically. The average seismic properties provide therefore an estimate of the maximum seismic anisotropy that could be produced, if the xenolith sampling is representative of the variability of compositions and CPO in the lithospheric mantle beneath the studied area.

4. Data

4.1. Microstructures

Previous studies (Fodor et al., 2002; Rivalenti et al., 2000; Rivalenti et al., 2007) have correlated optical observations of the microstructures with chemical compositions and equilibrium temperatures to divide the Macau peridotite xenoliths into two groups: protogranular and porphyroclastic. In the present study, we added to the optical observations the quantitative analysis of the microstructural data derived from EBSD mapping. Based on these data, in particular the intragranular misorientation of olivine and the olivine and orthopyroxene grain shapes (Fig. 2), we classify the Macau peridotites into three microstructural groups (Table 1): coarse-granular (6), coarse-porphroclastic (12), and fine-porphroclastic (4). The coarse-granular and coarse-porphroclastic groups correspond to a continuous variation in microstructure (Figs. 2 and 3). They were described as protogranular in the previous studies. The fine-porphroclastic group is clearly different from the other two groups (Figs. 2 and 3); it was described as porphyroclastic in

the previous studies.

There is no relation between microstructure and sampling site. All three microstructures are represented among the Pico do Cabugi peridotites, which is the best-sampled site in the present study, and in at least one of the other sampling localities (Table 1). This observation is corroborated by the previous studies, which analyzed a larger number of peridotite xenoliths from other Macau volcanic centers (Fodor et al., 2002; Rivalenti et al., 2007). Coarse granular and coarse porphyroclastic microstructures predominate in all sites. Fine-porphroclastic peridotites are always minor. They were only recovered in three sites, which are nevertheless > 60 km apart (Fig. 1): Serra Aguda, Cabugi, and Serrote Preto (a small plug ca. 30 km to the SSE of Pico do Cabugi, Fodor et al., 2002).

Coarse-granular peridotites are characterized by roughly equigranular microstructures (Fig. 3a–b). Olivine and orthopyroxene pyroxene grains are on average 1–3 mm, clinopyroxene slightly smaller: 0.8–1 mm (Table 2). Both olivine and pyroxenes have curvilinear to straight grain boundaries, evolving locally into polygonal shapes with 120° triple junctions (Fig. 4a), and very low densities of intracrystalline deformation features, such as undulose extinction, subgrains, or kinks (Figs. 3a and 4a). Quantitatively, these observations translate into low shape factors ≤ 1.85 for olivine and ≤ 2 for orthopyroxene and into low M2M values $\leq 2^\circ$ for olivine (Fig. 2). Lherzolite 16CA14 has an intermediate microstructure characterized by polygonal olivine grains, but pyroxenes with irregular shapes (Figs. 2 and 4b). Most coarse-granular peridotites display a weak olivine shape-preferred orientation (SPO)

Fig. 4. Photomicrographs in cross-polarized light displaying typical features for the three microstructural groups. (a) Coarse granular lherzolite displaying polygonal grains (black arrow marks a 120° triple junction) almost free of intracrystalline deformation features, white arrow indicates a relict subgrain boundary in olivine (ol). (b) Coarse granular lherzolite 16CA14 displaying polygonal strain-free olivine grains, but irregularly-shaped orthopyroxene (opx) grains (highlighted by dashed line). (c–d) Coarse porphyroclastic lherzolites 16CA11 and 16CA06 showing irregularly shaped olivine, orthopyroxene (highlighted by dashed line), and clinopyroxene (cpx) grains with interpenetrating inter-phase boundaries, white arrows indicate subgrain boundaries in ol in (c) and mark cusp shaped opx in contact with ol in (d). (e) Fine-porphyroclastic lherzolite AG6 showing a matrix of very fine recrystallized olivine neoblasts surrounding a coarse olivine porphyroclast with undulose extinction and subgrains (white arrow). (f) Fine-porphyroclastic harzburgite PC109 showing tabular, strain-free olivine neoblasts as well as relicts of olivine porphyroclasts with undulose extinction (white arrow) within a strongly recrystallized domain between opx porphyroclasts. Scale bar is the same in all photomicrographs.

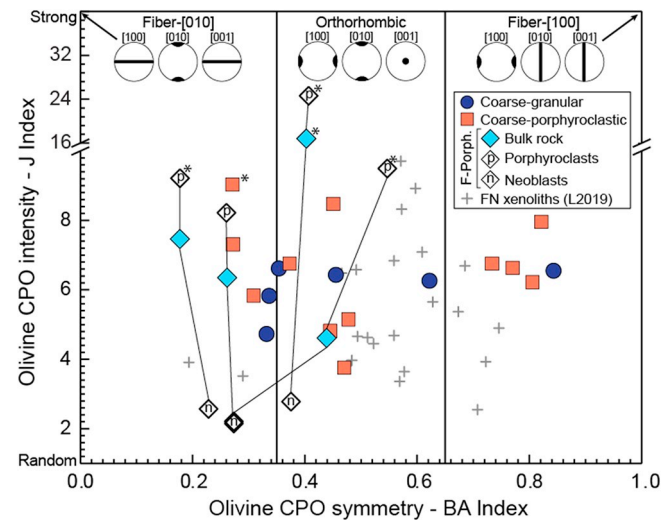

Fig. 5. Olivine CPO symmetry (BA-index) vs. CPO strength (J-index). The variation in olivine CPO pattern as a function of BA-index is illustrated at the top of the diagram. For fine-porphyroclastic peridotites, we present data for the bulk rock and for porphyroclasts and neoblasts separately. Values are presented in Table 2. * indicates J-indices that are probably overestimated, because < 100 grains could be analyzed in the thin section. CPO data for Fernando de Noronha (FN) xenoliths (Liu et al., 2019) are displayed for comparison.

(Fig. 3a), but B009 has higher olivine aspect ratios (Table 2) and a clear olivine SPO, which results in a tabular microstructure. Pyroxene grains usually show no exsolutions (Figs. 3a and 4a–b). Spinel grains have holy-leaf or interstitial shapes. Coarse holy-leaf spinels may contain rounded inclusions of olivine or pyroxenes (Fig. 3b).

Coarse-porphyroclastic microstructures are characterized by variable grain sizes. In most cases, the grain size variation is continuous and it is difficult to discriminate between porphyroclasts and neoblasts (Fig. 3c–d). Olivine has more irregular grain shapes and clear evidence for intracrystalline plastic deformation (Figs. 3c–d and 4c). Olivine grains have shape factors between 1.6 and 2.2, consistently with the more sinuous grain boundaries, and higher M2M values ranging from 2° to 3.4° (except 16CA15), consistent with the higher frequency of undulose extinction and subgrain boundaries (Fig. 2). Orthopyroxene grains also have irregular shapes (Figs. 3c–d and 4c–d), which are associated with shape factors from 1.6 to 2.4 (Fig. 2b). Orthopyroxene grain boundaries often show embayments or cusped shapes at the contact with olivine grains (Fig. 4c–d). Clinopyroxene grains also show irregular or interstitial shapes (Fig. 3c–d). In some samples, orthopyroxene grains display exsolutions (Fig. 3c). Undulose extinction and kinks are observed locally. Spinel usually has irregular shapes and occurs in association with ortho- or clinopyroxene (Fig. 3d).

Fine-porphyroclastic peridotites show a well-developed bimodal olivine grain size distribution, characterized by coexistence of coarse porphyroclasts with serrated grain boundaries, undulose extinction, and closely-spaced subgrain boundaries with a recrystallized matrix

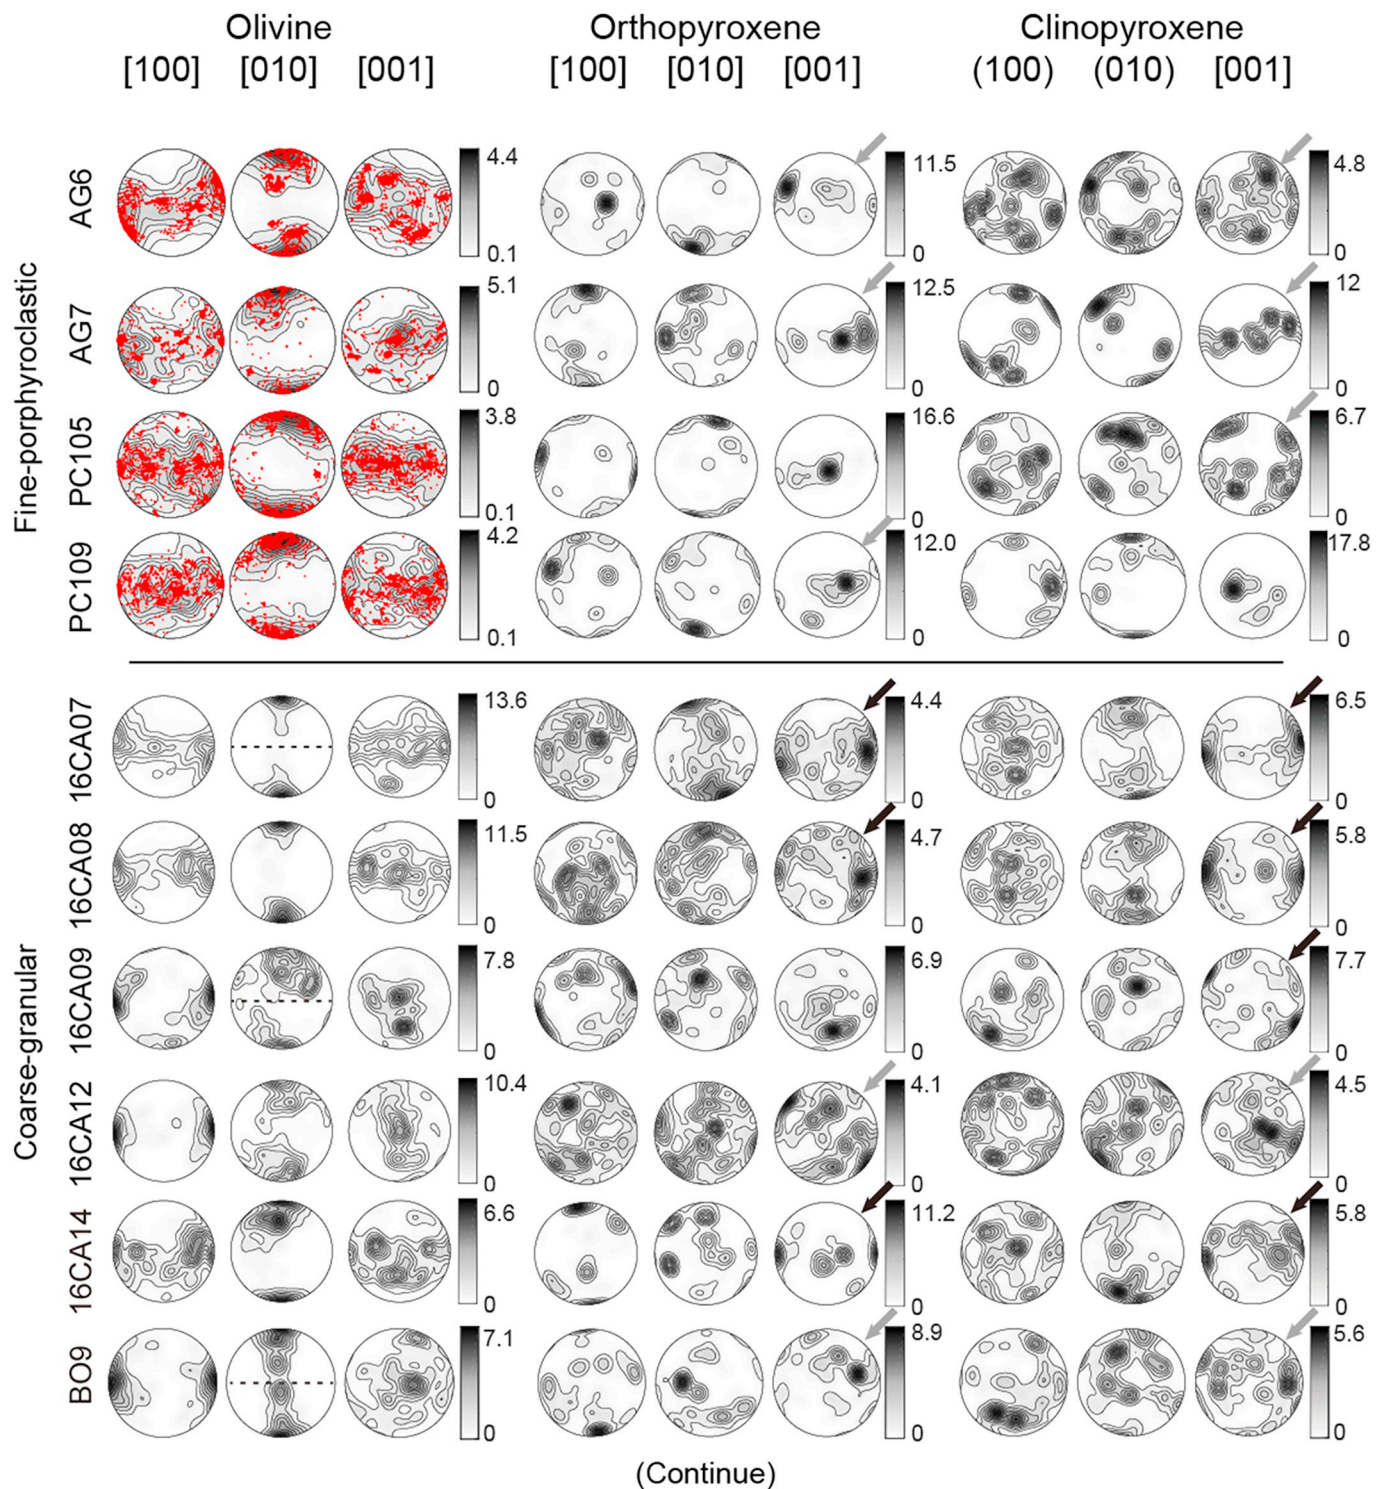

Fig. 6. Crystal preferred orientations (CPO) of olivine, orthopyroxene, and clinopyroxene for all studied fine-porphyroclastic, coarse-granular peridotites, and coarse-porphyroclastic peridotites. Lower hemisphere stereographic projections with contours at 1 multiple of a uniform distribution intervals. The three pole figures for each mineral are plotted using the same scale. For the fine-porphyroclastic peridotites, the CPO of olivine porphyroclasts is presented as points (in red) and the CPO of olivine neoblasts is presented as contours. Black arrows indicate pyroxene CPO that are well correlated with the olivine CPO and gray arrows indicate those partially correlated. When the sample shows an olivine shape preferred orientation marking a foliation, the latter is displayed as a dashed line in the olivine [010] pole figure. (For interpretation of the references to color in this figure, the reader is referred to the web version of this article.)

composed by polygonal olivine neoblasts free of intracrystalline deformation (Figs. 3e–h and 4e–f). The average size of the recrystallized grains varies between samples (Table 2): it is $\sim 100\ \mu\text{m}$ in AG6 (Fig. 4e), but $> 300\ \mu\text{m}$ in the other fine-porphyroclastic peridotites (Fig. 4f, Table 2). It is noteworthy that the recrystallized olivine grains are not

organized in a planar mode, marking a foliation, but either form irregular pockets or vein-like structures (Fig. 3e–f). Orthopyroxene is usually coarser than clinopyroxene (Fig. 3f). Exsolutions were not observed in this group. Shape factors of orthopyroxene vary between 1.89 and 2.56 (Fig. 2). In AG6 and AG7, pyroxenes have rounded shapes

Fig. 6. (continued)

(Fig. 3f), whereas in PC105 and PC109 fine-porphyroclastic samples, pyroxenes have irregular shapes, with cusp-like terminations when in contact with olivine, similarly to pyroxenes in coarse-porphyroclastic peridotites. Spinel occurs as fine rounded grains (Fig. 3f).

4.2. Crystallographic preferred orientations (CPO)

Quantitative data on the intensity and symmetry of the olivine CPO (J- and BA-indexes) as well as pole figures of the olivine, orthopyroxene, and clinopyroxene CPOs for all studied samples are presented in

Fig. 7. Modal compositions of the studied peridotites presented as clinopyroxene/orthopyroxene ratio vs. olivine modal content and as the traditional olpx-cpx ternary diagram (inset). Modal compositions of Cabugi and other Macau volcanics peridotite xenoliths studied by Rivalenti et al. (2000, 2007) are plotted for comparison. Black and gray curves represent the evolution of the modal composition predicted by different partial melting models for an initial fertile modal composition of 55% ol, 28.5% opx, and 16.5% cpx (Baker and Stolper, 1994; Kostopoulos, 1991; Niu, 1997; Walter et al., 1995). Gray arrows indicate evolution trends associated with cpx and/or opx crystallization at the expense of ol (refertilization reactions). Black arrows indicate evolution trends associated with ol crystallization at the expense of pyroxenes (dunitization reactions).

Figs. 5 and 6 and Table 2. For the samples in which a foliation was observed, the latter is displayed on the pole figures (Fig. 6). In these samples, the olivine [010] maximum is normal to the foliation.

Olivine has moderate to strong CPO (Figs. 5 and 6). With exception of harzburgite AG7, which has a very high J-index of 16.6 due to a few coarse olivine porphyroclasts that occupy most of the thin section, and lherzolite SV8 (small sample), the J-index varies between 3.8 and 8.5, with a mean of 6.4. The CPO symmetry varies between fiber-[010], orthorhombic, and fiber-[100] patterns. Fine-porphyroclastic peridotites display olivine CPO patterns intermediate between fiber-[010] and orthorhombic and the neoblasts have systematically weaker olivine CPO (Figs. 5 and 6). There is no systematic variation of J-index or BA-index within the two other microstructural groups. Most coarse-granular samples display orthorhombic olivine CPO patterns with J-indexes around 6 (Figs. 5 and 6). Coarse-porphyroclastic samples have more variable olivine CPO patterns and intensities (Fig. 5). Four coarse-porphyroclastic harzburgites (16CA01, 16CA02, 16CA03, and 16CA18) have strong CPO with fiber-[100] patterns (Fig. 6). The remainder coarse-porphyroclastic peridotites display olivine CPO of variable intensity and orthorhombic patterns with a tendency towards fiber-[010], expressed as girdle of [100] with a maximum within it and a point maximum of [010] (Fig. 6).

Orthopyroxene CPO is consistent with the olivine CPO in the majority of the studied peridotites. It is characterized by $[001]_{\text{opx}}$ and $[100]_{\text{opx}}$ (or $[010]_{\text{opx}}$) maxima parallel to the $[100]_{\text{ol}}$ and $[010]_{\text{ol}}$ maxima, respectively, suggesting a common deformation history (arrows in Fig. 6). However, coarse-porphyroclastic harzburgites 16CA01, 16CA02, 16CA03, 16CA18 and coarse-granular lherzolite 16CA09 show weak orthopyroxene CPO that are not consistent with the olivine CPO, characterized by a weak $[001]_{\text{opx}}$ maximum at high angle to a well-developed $[100]_{\text{ol}}$ maximum.

Clinopyroxene shows more dispersed CPO, but which are, in many samples, consistent with both olivine and orthopyroxene CPO patterns, characterized by $[001]_{\text{cpx}}$ and $[010]_{\text{cpx}}$ maxima subparallel to $[100]_{\text{ol}}$

and $[010]_{\text{ol}}$ maxima (arrows in Fig. 6). However, in most fine-porphyroclastic peridotites and in coarse-granular lherzolite 16CA12, although the orthopyroxene CPO is consistent with the olivine CPO, the clinopyroxene CPO is not. In coarse-porphyroclastic harzburgites (16CA01, 16CA02, 16CA03, 16CA18) neither the orthopyroxene nor the clinopyroxene CPO are correlated with the olivine CPO.

4.3. Modal compositions

All samples are spinel-facies peridotites. Lherzolites predominate (14/22), but the sampling also includes 7 harzburgites and 1 wehrlite (Fig. 7 and Table 1). Predominance of fertile peridotites with no dependence on sampling site was also observed in previous sampling of Macau xenoliths by Rivalenti et al. (2000, 2007; Fig. 7).

The compositions of the two microstructural groups overlap, but coarse-granular peridotites are on average more fertile (ol contents of 57–70%) than coarse-porphyroclastic peridotites (ol contents between 67 and 87%, with one outlier, 16CA04, which has 59% of olivine and an intermediate microstructure). Fine-porphyroclastic peridotites display variable olivine contents overlapping with the two other groups.

Comparison of the modal compositions to those predicted by various partial melting models highlights that roughly half of the studied Macau xenoliths are enriched in clinopyroxene or olivine relatively to the models' predictions (Fig. 7). Even for those samples plotting along the partial melting trends, a large variability in partial melting degrees, from 1 to 20% melting, has to be invoked to explain the full range of observed modal compositions. Such a variation in partial melting is difficult to reconcile within the limited volume of the mantle sampled by the volcanic eruptions. This suggests reactive melt percolation leading to either crystallization of clinopyroxene and/or orthopyroxene at the expenses of olivine (refertilization processes, e.g. Le Roux et al., 2007; represented by gray arrows in Fig. 7) or crystallization of olivine at the expense of pyroxenes (dunitization processes, e.g., Berger and Vannier, 1984; Kelemen, 1990; black arrows in Fig. 7). The observed deviations in modal compositions relatively to partial melting trends are consistent with microstructural evidence for reactive melt percolation, such as the sinuous olivine-pyroxene boundaries and the cusplike shapes of pyroxenes when in contact with two olivine grains (cf. Figs. 3 and 4).

4.4. Mineral compositions

The chemical compositions of main mineral phases in the studied Macau peridotite xenoliths are listed in Supplementary material Table S1. Representative results are displayed in Fig. 8 together with previous data for Macau peridotite xenoliths (Supplementary material Table S2). Comparison between the present and previous datasets indicates that our sampling is representative of the variability in composition for these localities. Analysis of the present dataset indicates that there is no simple correlation between microstructural types and chemical compositions (Fig. 8). There is also no relation between mineral chemistry and sampling locality.

The Mg# number [$\text{Mg\#} = 100 \times \text{Mg} / (\text{Fe} + \text{Mg})$, atomic ratio] of olivine, orthopyroxene, and clinopyroxene ranges between 89.1 and 91.6 (average 90.0), 89.1–91.7 (average 90.4), and 87.9–92 (average 90.9), respectively (Fig. 8a, b). Core-rim variations in Mg# are weak for all three minerals in most samples. Olivine and orthopyroxene Mg# within each sample show low dispersion and are positively correlated, with the orthopyroxene being slightly enriched in Mg relatively to olivine (all data points, except fine-porphyroclastic peridotites AG6 and AG7, plot slightly above the 1:1 line in Fig. 8b). Clinopyroxene Mg# shows much higher variability at the sample scale, in particular within coarse-porphyroclastic harzburgites, indicating chemical disequilibrium at the mm-scale. Moreover, average clinopyroxene Mg# in

Fig. 8. Chemical compositions for major rock-forming minerals: (a–c) Clinopyroxene Mg#, orthopyroxene Mg#, and olivine Ca content (ppm) vs. olivine Mg#, (d) Clinopyroxene TiO₂ content (wt%) vs. modal content (%). Minerals chemical compositions for Macau peridotite xenoliths previously studied by Rivalenti et al. (2000, 2007), and Fodor et al. (2002) are plotted for comparison. The value of the depleted mantle (DM) from Workman and Hart (2005) is displayed in (a) and (b). Fe-Mg partition between olivine and clinopyroxenes in troctolites (Lissenberg and Dick, 2008) is plotted in (a). Partial melting and refertilization trends proposed by Le Roux et al. (2007) are plotted in (d). Hollow symbols represent rim compositions and solid symbols represent core ones. Error bars represent the chemical variation at the sample scale. Data is presented in Supplementary material Table S1.

neither cores nor rims display any simple correlation with the olivine Mg# (Fig. 8a). Most measured Mg# spread between the 1:1 and the Fe-Mg partition trend between olivine, clinopyroxene, and melt in oceanic troctolites (Lissenberg and Dick, 2008), but fine-porphyroclastic peridotites AG6 and AG7 have clinopyroxenes enriched in Fe relatively to olivine.

Olivine cores show low Ca contents with a weak positive correlation with Mg# (Fig. 8c), except for the fine-porphyroclastic peridotites and the coarse-porphyroclastic lherzolite GR1, which have high Ca contents. Olivine rims in all studied peridotites are enriched in Ca and show a high variability at the thin section (mm-cm) scale.

Clinopyroxene TiO₂ contents (wt%) do not show the simple positive correlation with cpx modal content (%) expected if partial melting controlled the chemistry of the peridotites (Fig. 8d). Among the harzburgites, four have Ti-poor clinopyroxene (TiO₂ contents < 0.2%), while the other two have clinopyroxene with TiO₂ contents of 0.55%. All harzburgites show marked variability in the Ti-content of clinopyroxene at the sample scale, indicating disequilibrium. Half of the lherzolites have clinopyroxenes with almost constant TiO₂ contents between 0.55 and 0.65%, independently of the clinopyroxene modal content. The remaining lherzolites have rather Ti-poor clinopyroxene grains.

Spinel Cr# [$Cr\# = 100 \times Cr / (Cr + Al)$] and Mg# contents correlate with the modal composition. Harzburgites have spinel with Cr# ranging between 40 and 57.5 and Mg# ranging between 61 and 72, whereas lherzolites have spinel with Cr# between 8 and 20 and Mg# between 73 and 84 (Supplementary material Fig. S1a). Yet, the lherzolites show a clear enrichment in Mg in spinel relatively to a typical depleted mantle composition. Fine-porphyroclastic lherzolite AG6 has the highest spinel Mg# (83) and lowest Cr# (11). TiO₂ contents (wt%) in spinel are low ($\leq 0.18\%$) in most lherzolites (Supplementary material Fig. S1b). In contrast, spinel in coarse-porphyroclastic harzburgites and lherzolite GR1 has a wide range of average TiO₂ contents, which may reach 1.03%, with strong variations within each sample, indicating disequilibrium. Spinel in fine-porphyroclastic lherzolite AG6 also has a fairly high TiO₂ content of 0.45%.

4.5. Equilibrium temperatures and geotherm estimation

Most equilibrium temperatures determined using two-pyroxenes geothermometer of Taylor (1998; TTA98) and the Ca in orthopyroxene (Ca-in-opx) of Brey and Kohler (1990) revised by Nimis and Grutter (2010) agree within ± 70 °C (gray dashed lines in Fig. 9). This suggests that they are reliable. However, peridotites with cpx-opx

temperatures < 800 °C show larger discrepancies (> 90 °C), with systematically higher Ca-in-opx equilibrium temperatures. This inconsistency between the predictions of the two thermometers is observed for both core and rim temperatures and is not correlated with the microstructure. It affects two coarse-porphyroclastic peridotites (16CA06, 16CA11) and one coarse-granular lherzolite (16CA14). The latter has the lowest temperature among all samples with strong inconsistency between the predictions of the two thermometers (592 °C and 790 °C, Table 1).

Fig. 9. Average core and rim equilibrium temperatures calculated using the cpx-opx thermometer (TTA98, Taylor, 1998) and the Ca-in-opx thermometer (Ca-in-opx, Brey and Kohler, 1990, revised by Nimis and Grutter, 2010). Chemical compositions from Rivalenti et al. (2000, 2007) and Fodor et al. (2002) were used to recalculate the equilibrium temperatures for their samples using the same thermometers (data is presented in Supplementary material Tables S2 and S3). Error bars represent data spread within each sample. Gray dashed lines outline a ± 70 °C variation between the two thermometers.

Following Nimis and Grutter (2010), we use the temperature predictions of TTA98 thermometer as the equilibrium temperatures. All fine-porphyroclastic peridotites and the coarse-porphyroclastic peridotite GR1 have high equilibrium temperatures over 1200 °C. Coarse-porphyroclastic peridotites have two ranges of equilibrium temperatures: harzburgites (16CA01, 16CA03, 16CA18) as well as clinopyroxene-poor lherzolite SV8 have equilibrium temperatures between 900 and 1100 °C, whereas the clinopyroxene-rich coarse-porphyroclastic lherzolites (16CA06, 16CA11, 16CA15) have lower equilibrium temperatures between 600 and 700 °C. Coarse-porphyroclastic peridotites 16CA03, 16CA15, and 16CA18 display core-rim variations in equilibrium temperature. In most cases, rim Ca-in-opx temperatures are higher than core ones, but there is no systematic trend. All samples that display core-rim variations also show significant dispersion in both core and rim temperatures at the sample scale (bars in Fig. 10). Coarse-granular peridotites 16CA07, 16CA08, 16CA09, and BO9 have intermediate equilibrium temperatures between 800 and 900 °C and less variations at sample scale as well as between cores and rims. Comparison with previous thermometry data on Macau peridotite xenoliths indicates that the present sampling is representative of the variability in this suite (Fig. 9). Analysis of the full dataset also highlights that there is no relation between equilibrium temperatures and sampling site. The full range of equilibrium temperatures is observed both among Pico do Cabugi xenoliths, which is the best sampled site, and among xenoliths from other Macau volcanics.

Fig. 10. P-T diagram comparing the equilibration conditions estimated for the studied Macau xenoliths to two possible steady-state geotherms for the north Borborema province (surface/reduced heat flows indicated in parenthesis). Xenolith data is better fitted by the hotter geotherm (surface and reduced heat flows of 75 and 45 mW/m², respectively). Since no barometers are available for spinel peridotites, equilibrium pressure ranges are presented as bars, based on the absence of plagioclase and of garnet in the studied peridotites, considering their Cr# (Supplementary information Table S1) and the effect of Cr on the spinel-garnet phase transition (Klemme, 2004; O'Neill, 1981). Dry and wet solidus with variable H₂O contents after Ringwood (1975). Moho and Lithosphere-Asthenosphere Boundary (LAB) depths derived from S-P and P-S receiver function analyses (Almeida et al., 2015, Heit et al., 2007) as well as partial melting conditions derived from the primitive melt compositions of the Cretaceous Ceará-Mirim dyke system (CMDS) and Cenozoic Macau volcanics (Ngonge et al., 2016a,b) are displayed for comparison. (For interpretation of the references to color in this figure, the reader is referred to the web version of this article.)

To estimate the Cenozoic geotherm in the northern Borborema Province, we plotted the TTA98 equilibrium temperatures of the studied xenoliths against the peridotite phase diagram in the upper mantle (spinel-out, plagioclase-out, and garnet-in curves for different Cr contents from O'Neill, 1981 and Klemme, 2004), as well as equilibrium geotherms for different surface and reduced heat flows (Fig. 11). The geotherms are calculated assuming a surface heat flow of 60 or 70 mW/m² (Hamza et al., 2018), a Moho depth of 32 km (Almeida et al., 2015), an exponential decrease of the radiogenic heat production with depth, with a characteristic depth of 10 km, and a reduced heat flow of either 30 or 45 mW/m². For comparison, we also indicate the depth of the lithosphere-asthenosphere boundary determined by S receiver functions for seismic station RCBR (Heit et al., 2007) and the partial melting conditions estimated based on the compositions of the most primitive melts of the Cenozoic Macau and Mesozoic Ceará-Mirim suites (Ngonge et al., 2016a,b).

P-T equilibrium conditions of the peridotites are displayed as a fixed temperature corresponding to the TTA98 thermometry prediction, but as a pressure range, because there are no reliable barometers for spinel-facies peridotites. The range of equilibrium pressure conditions is defined by the occurrence of spinel in absence of plagioclase or garnet for the actual Cr content of each peridotite (O'Neill, 1981; Klemme, 2004).

The wide range of equilibrium temperatures suggests that the studied peridotites represent a complete sampling of the subcontinental lithospheric mantle. The absence of garnet in the entire suite, which is largely composed of peridotites with Cr# < 15, constrains a maximum equilibrium depth of the studied peridotites shallower than 75 km (Fig. 10). By consequence, the equilibrium conditions of the Macau peridotite xenoliths, except 16CA14 that has the lowest and likely unreliable equilibrium temperature, are better fitted by the hotter geotherm (green line in Fig. 10).

4.6. Seismic properties

For calculating seismic properties, we divided the xenoliths into two groups as a function of their TTA98 equilibrium temperature: low ($T < 1000$ °C) and high-temperature ($T > 1000$ °C). Then, we estimated the elastic tensors of the individual samples (Supplementary material Table S3) for the pressure and temperature conditions predicted at 50 km (1.46 GPa and 916 °C) and 70 km depth (2.12 GPa and 1189 °C) for the geotherm that best fits the xenolith data ($Q_s = 70$ mW/m² and $Q_m = 45$ mW/m², green line in Fig. 10).

Seismic anisotropy patterns of the individual samples vary slightly as a function of the olivine CPO symmetry. As usual, the seismic anisotropy intensity correlates positively with both the olivine CPO strength and olivine modal content (Fig. 11). On average, the peridotites equilibrated at temperatures < 1000 °C tend to display lower anisotropy, due to both more dispersed olivine CPO and lower olivine contents. However, seismic anisotropy intensity does not increase linearly with increasing J-index. By consequence, overestimation of the olivine CPO intensity for fine-porphyroclastic harzburgite AG7 does not

result in similar overestimation of its seismic anisotropy. The maximum S-wave polarization anisotropy varies from 5.5 to 7.3% in the low-temperature peridotites and from 5.9 to 10% in the high-temperature ones (Fig. 11 and Table 3). Similarly, the maximum P-wave propagation anisotropy varies from 7.4 to 10% and from 7.7 to 14.2% (Table 3). The maximum fast (S1) wave propagation anisotropy varies from 3.0 to 5.9% in low-temperature samples and from 4.1 to 7.2% in high-temperature ones, whereas the maximum slow (S2) wave propagation anisotropy varies from 3.4 to 5.2% and from 1.9 to 7.3%, respectively (Table 3).

Since seismic waves average elastic properties over large volumes, we calculated average elastic tensors for the low-temperature and high-temperature groups by assuming a coherent orientation of the past flow directions and planes (assumed as parallel to the [100] and [010] maxima of the olivine CPO, respectively; this assumption is justified by the analysis of the CPO as discussed in the next section) over the entire lithosphere. These average seismic anisotropy patterns (Fig. 12) represent the maximum possible seismic anisotropy in the shallow (low-temperature group) and deep (high-temperature samples) sections of

Fig. 11. Maximum S-wave polarization anisotropy (%) vs. (a) olivine CPO intensity (J index) and (b) olivine modal content (%) for all studied xenoliths. Seismic anisotropy data for individual samples are listed in Table 3.

Table 3

Calculated seismic properties for the individual and for the average low- and high-temperature Macau peridotites.

the lithospheric mantle, if the present sampling is representative of the volumes of the different microstructures and compositions in the lithospheric mantle in this region.

produced the CPO was followed by annealing (static recrystallization), which effectively reduced dislocation densities and re-equilibrated grain shapes. The analysis of the relative intensity of the orientation of

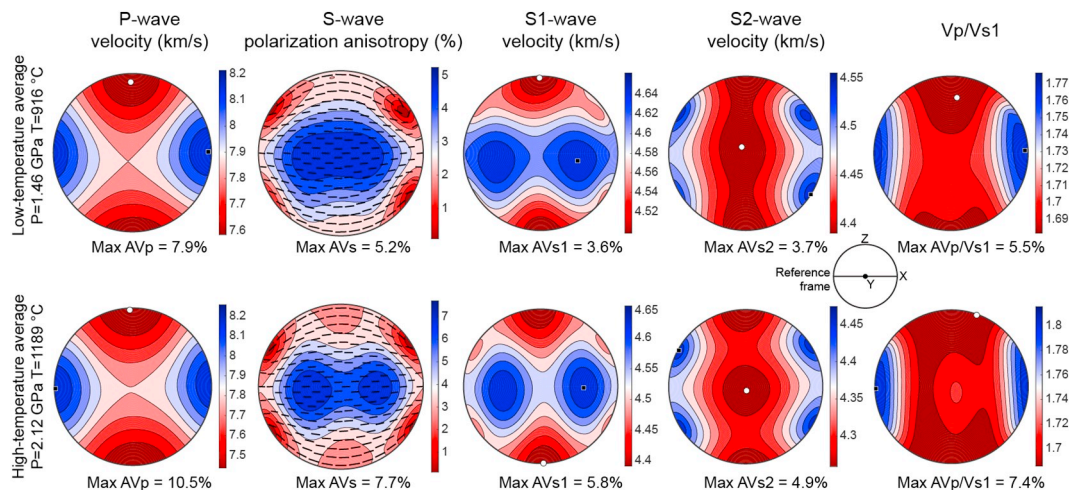

Fig. 12. Average seismic properties for shallow and deep sections of the lithospheric mantle beneath the study area calculated by averaging the elastic constant tensors of the eight low-temperature samples calculated for 916 °C, 1.46GPa and of the nine high-temperature samples calculated for 1189 °C, 2.12GPa. Lower hemisphere stereographic projections presenting the variation of the property as a function of the propagation direction relatively to the structural reference frame (flow direction (X) and normal to the flow plane (Z) shown by the inset). Black squares mark the highest values and white circles mark the lowest ones. Seismic properties data are listed in Table 3 and the elastic tensors, in Supplementary material Table S4.

Seismic anisotropy patterns for the shallow and deep lithospheric mantle are similar, but as already discussed, the lower part of the lithosphere is more anisotropic (Fig. 12). The average maximum P-wave propagation anisotropy is 10.5% with velocities ranging between 7.4 and 8.3 km/s, compared to 7.9% in the shallow lithospheric mantle, where P-wave velocities vary between 7.6 km/s normal to the flow plane and 8.2 km/s parallel to the flow direction frozen in the lithospheric mantle (Table 3). The average maximum S-wave polarization anisotropy in the lower lithospheric mantle is 7.7% compared to 5.2% in the shallower levels; in both cases it is observed for S-waves propagating within the flow plane but at < 45° of the flow direction. Low S-wave polarization anisotropy is observed for all waves propagating at low angle to the XZ plane, that is, the plane that contains both the flow direction and the normal to the flow plane. For all propagation directions in which a significant polarization anisotropy is observed, the fast S-wave is polarized in the plane containing the flow direction. The average maximum S1-wave propagation anisotropy increases from 3.6% to 5.8% from the shallow to the deep mantle lithosphere. S1 velocity is maximum within the flow plane and minimum normal to it. S1-waves propagating within this plane show a 90° periodicity in the velocity variation. S2-waves average maximum propagation anisotropy increases from 3.7% to 4.9% with depth. High S2 velocities are associated with propagation within the XZ plane at ca. 45° to the flow direction (X) and low velocities are observed for all propagation directions at high angle to X. The maximum Vp/Vs1 ratio anisotropy increases from 5.5% to 7.4% with depth. Highest Vp/Vs1 ratios (1.78–1.8) are observed for waves propagating parallel to the flow direction and the lowest Vp/Vs1 ratios for waves propagating normal to the flow plane.

5. Discussion

5.1. Deformation, annealing, and reactive melt percolation

Coarse-granular peridotites show polygonal grain shapes for both olivine and pyroxenes and low intragranular misorientations (olivine M2M values < 2°, Fig. 2). However, they have well-developed olivine CPO (Figs. 5 and 6). This association supports that the deformation that

[100], [010], and [001] of olivine, of the relations between olivine and pyroxene CPOs, and of the relations between olivine CPO and SPO (when a SPO was observed) points to deformation by dislocation creep with dominant activation of the [100](010) slip system in olivine, [001](100) in orthopyroxene, and [001](0kl) in clinopyroxene (Tommasi et al., 2000; Bascou et al., 2002). Coarse-granular peridotites have roughly constant olivine CPO intensities, but variable symmetry, covering the entire range from fiber-[100] to fiber-[010]. Fiber-[100] and orthorhombic olivine CPO are the usual patterns produced by simple shear under dry, high to moderate temperatures, and low pressure in the upper mantle (Tommasi et al., 1999, 2000; Hansen et al., 2014). Fiber-[010] patterns, on the other hand, require particular conditions, which may be: transpression (Tommasi et al., 1999), presence of melts during the deformation (Higgie and Tommasi, 2012, 2014; Qi et al., 2018), changes in the olivine CPO by oriented growth during recrystallization (e.g., Tommasi et al., 2008), or deformation under high stress or high pressure conditions, which would lead to increased activation of [001] glide (Durham and Goetze, 1977; Mainprice et al., 2005; Demouchy et al., 2013). The mineralogy and microstructures and CPO of the coarse-grained peridotites falsify the last hypothesis. However, the present data does not allow for discriminating among the other hypotheses. The different olivine CPO symmetry may therefore result from variations in deformation regime, with fiber-[010] CPO recording transpression (which is the dominant deformation regime in the Seridó belt during the Brasiliano event), presence or not of melts during the deformation (all deformation events were accompanied by magmatism), or different CPO evolution during recrystallization.

Analysis of the bulk rock Mg# vs. olivine modal content relation (Fig. 13) shows that the compositions of most coarse-granular peridotites deviate from partial melting trends, suggesting the occurrence of refertilization processes. Yet, most coarse-granular peridotites have coherent olivine and pyroxene CPOs (Fig. 6), which indicate co-deformation of the two phases. Thus, if melt-rock reactions leading to refertilization occurred, they predated or were concomitant to the deformation. Refertilization reactions produce sutured pyroxene-olivine boundaries and irregular shapes for both minerals. The equilibrated pyroxenes grain shapes in most coarse-granular peridotites indicate

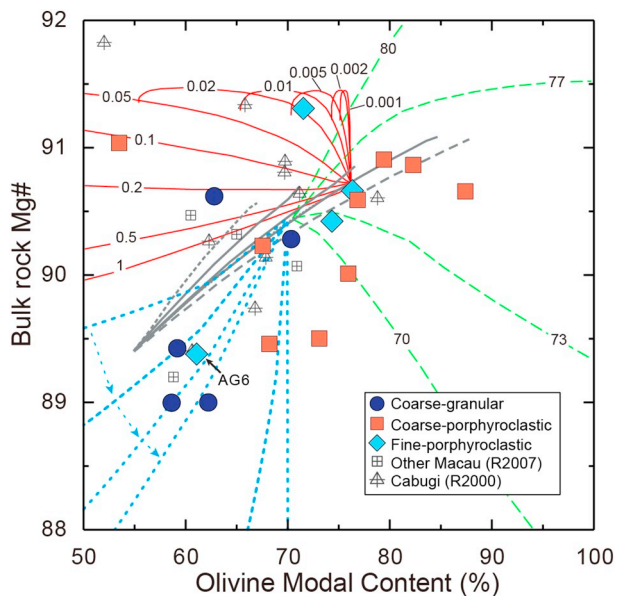

Fig. 13. Olivine modal content (%) vs. bulk rock Mg# in the studied xenoliths compared to evolutions predicted for partial melting and reactive melt percolation in the mantle. Gray lines represent the composition evolution predicted by various partial melting models using a source composition with 89.3 Mg# and 55% of olivine up to complete consumption of clinopyroxene (Bodinier and Godard, 2014). Colored lines represent different melt-rock reactions after Bodinier and Godard (2014). Red solid lines correspond to precipitation of clino- and orthopyroxene at the expense of olivine and melt with different mass ratio of crystallized minerals versus infiltrated melt (numbers on the curves). Green dashed lines show olivine-forming reactions with melts with different Mg# (numbers on the curves). Blue dotted lines represent multiple episodes of refertilization, starting with low Mg# melts ('primitive' melt Mg# = 74.5), in which the peridotites successively reacted with the evolved melt resulting from previous infiltration stage (Bodinier et al., 2008). Compositions of Macau peridotite xenoliths previously studied by Rivalenti et al. (2000, 2007) are plotted for comparison. (For interpretation of the references to color in this figure legend, the reader is referred to the web version of this article.)

therefore that reactive melt percolation producing refertilization also predated annealing. It also implies that interphase grain boundary rearrangements during annealing were effective. These rearrangements depend on transport of ions along grain boundaries in a similar way to the growth of porphyroblasts in a metamorphic rock, but with weaker driving forces (grain boundary energy reduction opposed to chemical gradients). Most coarse-granular peridotites equilibrated around 900 °C (Fig. 9). At this temperature, given the diffusivity of Si along olivine and enstatite grain boundaries ($\leq 10^{-27} \text{ m}^2/\text{s}$; Fisler et al., 1997; Fei et al., 2016), grain boundary equilibration at the 250 μm scale, which is the average amplitude of the sinuosity of the olivine-pyroxene grain boundaries in the coarse-porphyroclastic peridotites (Fig. 3c, d), will occur on time scale of several hundreds of Ma. In contrast, irregular pyroxene grain shapes (high orthopyroxene shape factor $\sim 2^\circ$, Fig. 2) in 16CA14 and BO9 point to a later stage of melt percolation. Indeed, in both samples, part of the pyroxenes shows crystal orientations not coherent with the olivine CPO (Fig. 6).

Coarse-porphyroclastic peridotites show less equilibrated microstructures. All major phases show sinuous grain boundaries (higher shape factors) as well as undulose extinction and subgrains, which translate into higher M2M values (Fig. 2). This implies less effective annealing due to either more recent deformation or lower post-deformation temperatures. The former hypothesis may apply for the coarse-porphyroclastic peridotites with high equilibrium temperatures ($\geq 1000^\circ\text{C}$, Fig. 9) and the latter, for those with low equilibrium temperatures ($< 800^\circ\text{C}$, Fig. 9). Similarly to the coarse-granular peridotites, olivine CPO in coarse-porphyroclastic peridotites is consistent

with deformation by dislocation creep with dominant activation of the [100](010) system. This interpretation is corroborated by the high frequency of (100) subgrain boundaries. However, the CPO patterns and intensities are more varied than those of coarse-granular peridotites (Figs. 5 and 6). Coarse-porphyroclastic harzburgites have strong fiber-[100] olivine CPOs, typical of simple shear deformation (Tommasi et al., 1999, 2000; Bystricky et al., 2000; Hansen et al., 2014). Lherzolites have orthorhombic to fiber-[010] olivine CPOs with variable strength. As for the coarse-granular peridotites, the fiber-[010] olivine in these coarse-porphyroclastic peridotites may record either a component of transposition or the presence of melts during deformation.

Although some coarse-porphyroclastic peridotites plot along partial melting trends in Fig. 13, evidence for reactive melt percolation leading to crystallization of pyroxenes or olivine is widespread in this microstructural group. It encompasses: (i) the interpenetrating olivine-pyroxene grain boundaries and the locally interstitial shapes of pyroxenes (Figs. 3 and 4), which imply lack of microstructural equilibrium, (ii) the high variability of the olivine and pyroxenes chemical compositions both within grains and between grains in a sample (Fig. 8), which indicates absence of chemical equilibration, and (iii) the lack or weak consistency between the olivine and the pyroxenes CPOs (Fig. 6). The latter feature is specific to the coarse-porphyroclastic harzburgites, which also show the highest equilibrium temperatures and least equilibrated mineral compositions among the coarse-porphyroclastic peridotites, implying that reactive melt percolation in these rocks, which sample the lower lithospheric mantle section, postdates the deformation and is rather recent.

Fine-porphyroclastic peridotites show a bimodal olivine grain size distribution and strong intragranular misorientations in the olivine porphyroclasts characteristic of recrystallization (Figs. 3 and 4). At the high equilibrium temperatures recorded by these peridotites ($\geq 1200^\circ\text{C}$, Fig. 9), diffusion is fast. The low annealing level of the microstructures in these peridotites, indicated by the high intragranular misorientations in the porphyroclasts (Figs. 2 and 3), implies therefore that the deformation episode that produced the recrystallization shortly predated their extraction from the mantle by the Macau volcanism.

The variation in recrystallized grain sizes between the various fine-porphyroclastic peridotites might record variations in stress (from ~ 75 MPa in AG6 to ~ 10 MPa using the recrystallized grain size paleopiezometer of Van der Wal et al., 1993), but the coarser recrystallized grain sizes result more probably from partial annealing. The stresses estimated for lherzolite AG6 are high and, for the equilibrium temperature of 1200°C of these peridotites, imply extremely high strain rates of 10^{-6} to 10^{-9} s^{-1} based on usual olivine flow laws (Chopra and Paterson, 1981; Hirth and Kohlstedt, 2003; Gourié et al., 2019). The microstructure of these peridotites is indeed very similar to the mosaic microstructure of deep sheared kimberlite-borne peridotites, which has been traditionally attributed to the initial stages of kimberlite dyke formation, due to the high stresses and high rates inferred based on the recrystallized grain sizes and equilibrium temperatures (e.g., Green and Gueguen, 1974; Boullier, 1977; Skemer and Karato, 2008; Baptiste et al., 2012). Similar microstructures have been observed in the deepest mantle xenoliths from the Labait alkaline lavas in the Tanzanian craton (Vauchez et al., 2005) and from Malaita alnoites in the Ontong Java plateau (Tommasi and Ishikawa, 2014) with similar interpretations proposed.

Fine-porphyroclastic peridotites with high equilibration temperatures have also been described in Cenozoic peridotite xenoliths, which sample the mantle beneath major Neoproterozoic shear zones at the border of the Hoggar swell, North Africa (Kourim et al., 2015). However, in the Hoggar peridotites, equilibration temperatures are lower ($1000\text{--}1100^\circ\text{C}$) and olivine recrystallization was associated with crystallization of elongated aggregates of clinopyroxene and amphibole. The fine-porphyroclastic microstructures were therefore interpreted as resulting from ductile reactivation and melt channeling in Neoproterozoic shear zones in response to the development of the Hoggar swell in

the Cenozoic. However, in the fine-porphroclastic peridotites from the Borborema province, there is no evidence for neocrystallization of pyroxenes or amphiboles within the recrystallized domains. Moreover, the fact that the recrystallized domains in the fine-porphroclastic peridotites from the Borborema province do not align marking a foliation (Fig. 3e, f) and the lack of elongation of the pyroxenes suggests that the recrystallization was associated with high stresses, but low finite strains. This association further points to localized deformation associated with the formation of the dykes that fed the Cenozoic magmatism.

Analysis of the olivine modal composition relative to the bulk rock Mg# implies that lherzolites AG7 and AG6 were affected by refertilization processes (Fig. 13). The Fe-rich compositions of olivine and pyroxenes in AG6 (Fig. 8a, b) imply high cumulated melt-rock ratios. Ortho- and clinopyroxenes in these two lherzolites have unusual irregular, but rounded shapes, which clearly differ from those in coarse-porphroclastic peridotites (cf. EBSD phase maps in Fig. 3). Yet determining when this refertilization occurred is difficult. At the high temperatures at which these peridotites equilibrated, chemical diffusion is fast. Disequilibrium in mineral chemistry at the sample scale, which would point to melt-rock interaction shortly before extraction is only observed in AG7. In contrast, harzburgites PC105 and PC109 plot along the partial melting trends in Fig. 13 and have high Mg# in olivine and pyroxenes (Fig. 8a, b), characterizing refractory compositions. They display, nevertheless, chemical evidence for some melt-rock interaction, like enrichment in Ca in olivine (Fig. 8c).

5.2. Cenozoic geotherm and thermal evolution of the NBP lithospheric mantle

We do have evidence in this study supporting a rather hot Cenozoic geotherm beneath the North Borborema Province. As illustrated in Fig. 10, equilibrium conditions of the xenoliths are consistent with the surface heat flow of 60–70 mW/m² measured in the Borborema Province (Hamza et al., 2018) if the heat flow from the convective mantle is rather high (45 mW/m²). This implies a slightly hotter than average sublithospheric mantle beneath the Borborema Province, consistently with the low P-wave velocity anomaly imaged at 100 km depth beneath the Northern Borborema Province east of the Macau-Queimadas volcanic alignment (Simões Neto et al., 2019; Fig. 1) and with the weak low S-wave velocity anomaly imaged beneath this region in a recent global full-waveform tomography model (ca. -2%; French et al., 2013). The equilibrium geotherm that best fits the equilibrium temperature and pressure conditions of the Borborema Province is also consistent with the seismological constraints for the lithosphere-asthenosphere boundary (LAB) depth of 80 km (Heit et al., 2007), with the Pn velocities of 8.0 km/s observed using refraction data (Lima et al., 2015) that imply sub-Moho temperatures of 700–750 °C, and with the partial melting conditions calculated for the Macau most primitive basalts (1330–1415 °C at 80–93 km; Ngonge et al., 2016b; cf. Fig. 10). A hotter than average sublithospheric mantle may also account for the Cenozoic uplift of the Borborema Plateau (Almeida et al., 2015; Luz et al., 2015; Klöcking et al., 2018). The equilibrium temperatures of the studied xenoliths may therefore represent an equilibrium geotherm established in the Cenozoic in response to a slightly hotter than normal convective mantle temperature. Geophysical data imply that these conditions are still active today. Data on the xenoliths do not bring any constraints on the causes of the higher than average sublithospheric temperatures, which may result from a diffuse mantle upwelling, perturbation of the convective pattern by the São Francisco craton, or, as suggested by Simões Neto et al. (2019), lateral channeling of hot material from a mantle plume upwelling to the SW of the Province.

The present data also do not constrain the evolution through time of the upper mantle temperatures beneath the North Borborema Province. The estimated melting conditions for the most primitive basalts of the Cretaceous CMDS (ca. 1320 °C at 70 km depth; Ngonge et al., 2016a)

are shallower than those for the Cenozoic Macau volcanics (Ngonge et al., 2016b), suggesting an even shallower LAB beneath the North Borborema Province in the Mesozoic. This suggests that the lithosphere beneath the NBP has probably cooled and thickened after the Mesozoic extension. The deepest xenoliths might therefore represent material accreted to the base of the lithosphere after the Mesozoic.

5.3. Seismic anisotropy in the lithospheric mantle: comparison with SKS splitting data

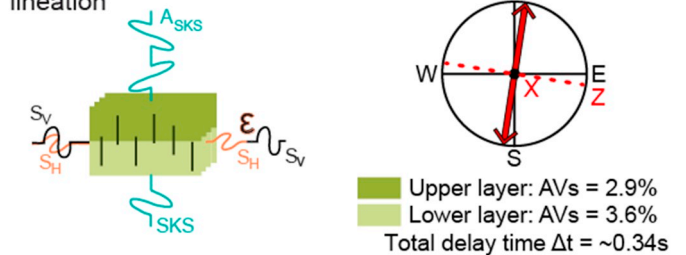

Shear wave splitting data in the Borborema Province is highly heterogeneous and does not relate in a simple way to neither the outcropping geological structures nor the absolute plate motion of the South American plate (Bastow et al., 2015). However, the station RCBR, which is the closest station to the sampling sites, being located ca. 50 km east of the Pico do Cabugi, displays a NNE-oriented fast S-wave polarization parallel to the trend of the Seridó belt and of the main Brasiliano shear zones in the region, and a high delay time (1.9 s) based on 9 individual measurements (Assumpção et al., 2011).

If we consider that at least part of the SKS splitting measured at RCBR is produced in the lithospheric mantle, the orientation of the fast polarization direction constrains the projection of the lineation on the horizontal plane to be oriented in the NNE direction ($9 \pm 11^\circ$). However, there are no constraints on its plunge or on the dip of the

Case 1: Horizontal foliation

Case 2: Vertical foliation & lineation

Case 3: Vertical foliation & horizontal lineation

Fig. 14. Estimates of the maximum SKS splitting that may be produced in the lithospheric mantle for three end-member orientations of the flow directions and planes. Stereographic projections show the relation between the geographic (in black) and the structural (in red) reference frames in the three cases. The vertical is in all cases at the center of the diagram. The orientation of the fast SKS polarization (thick red arrow) is based on SKS splitting data for station RCBR. (For interpretation of the references to color in this figure legend, the reader is referred to the web version of this article.)

foliation. To draw constraints on the orientation of the foliation and lineation in the lithospheric mantle, which would allow to discuss possible coupling between crustal and mantle structures, we estimate the contribution of the lithospheric mantle to the SKS splitting delay time (Δt) for three end-member orientations of the foliation and lineation in the lithospheric mantle, illustrated in Fig. 14, and compare these predictions to the observations at RCBR.

Common conversion point (CCP) receiver function stacks support that the Moho is at ~ 32 km (Almeida et al., 2015) and the LAB is at ~ 80 km based on the S receiver function data by Heit et al. (2007) in the Northern Borborema Province. The thickness of the lithospheric mantle in this region is therefore of 48 km. Based on the thermobarometric data (Fig. 10), we divided the lithosphere into two layers and calculated the lithospheric mantle contribution to the measured delay time using the average seismic anisotropy of the low temperature peridotites (32–56 km, < 1000 °C) and of the high-temperature ones (56–80 km, > 1000 °C).

If the foliation is horizontal and the lineation NE-SW (case 1), the S-wave polarization anisotropy is 2.4% for upper lithospheric mantle and 3.0% for lower lithospheric mantle. The cumulated SKS delay time is only ~ 0.30 s. If both the foliation and lineation are vertical (case 2), the fast SKS polarization constrains the direction of the foliation, and SKS waves propagate parallel to the lineation. The S-wave polarization anisotropy in this direction is low, like in case 1. It is 2.9% for upper layer and 3.6% for lower one and the delay time that may be cumulated in the lithospheric mantle is ~ 0.34 s. If the foliation is vertical but the lineation is horizontal and parallel to the fast SKS polarization direction (case 3), the S-wave polarization anisotropy is higher. It is 5.2% in the upper lithospheric mantle and 6.6% for lower lithospheric mantle, leading to a cumulate delay time in the lithospheric mantle of 0.64 s.

In case 3, the lithospheric mantle has a fabric consistent with the crustal deformation around station RCBR, which is dominated by dextral strike-slip in transpressional structures in the Seridó belt and in the shear zones that border it. This case would therefore imply a structuration in the lithospheric mantle coherent with the crustal deformation in the Brasiliano event. Seismic anisotropy in the lithospheric mantle, with anisotropy directions parallel or subparallel to the main nearby Neoproterozoic shear zones, is also required by receiver function analysis on most stations in the Borborema Province (Lamarque and Julià, 2019). At station RCBR, this study proposes horizontal anisotropy axis trending NNE in the lithospheric mantle, consistent with case 3.

It is important to note that even for case 3, the lithospheric mantle can contribute to $< 1/3$ of the SKS delay time measured at the RCBR station (1.9 ± 0.2 s, Assumpção et al., 2011). Thus a large part of the SKS signal at RCBR has to be produced in the asthenosphere and, for the contributions of the lithosphere and asthenosphere to add up, asthenospheric flow directions should not deviate much from NNE. Present-day absolute plate motion (APM) directions for NE Brazil do not follow this direction. Hotspot reference frame models, such as HS3-Nuvel-1A, predict an ENE direction, whereas no-net rotation models predict a NNW direction (Gripp and Gordon, 2002). However, a NNE flow direction in the sublithospheric mantle beneath the Borborema province is predicted by models in which the present-day mantle flow is calculated based on a density anomaly distribution derived from global seismic tomography models (cf. Fig. 8 in Assumpção et al., 2011).

5.4. Relations between the mantle structure and the geodynamical evolution of the Borborema Province

When did the deformation, annealing, and reactive melt percolation processes recorded by the xenoliths happen? How do they relate to the geodynamical evolution of NE Brazil? There are no ways of dating deformation processes in the mantle. However, we may try to use the data discussed in the previous sections to constrain the imprint of the different tectonic events that affected the Borborema Province in the

lithospheric mantle.

The coarse-granular microstructures, with their well-equilibrated pyroxene-olivine grain boundaries, imply effective annealing, which, at the equilibrium temperatures of these xenoliths, require very long time delays, on the order of several hundreds of Ma. Although the temperature may have varied since the deformation of the xenoliths, to re-equilibrate the pyroxene-olivine grain boundaries in < 100 Ma, temperatures ≥ 1100 °C, that is > 200 °C above those recorded by the xenoliths at the time of extraction, are needed. Coarse-granular microstructures are well expressed among the low-equilibrium temperature xenoliths, suggesting that the shallow part of the lithospheric mantle beneath the Macau volcanics records essentially old tectonic events. The seismic anisotropy data in the region imply that this lithospheric structure results from Neoproterozoic dextral strike-slip and transpressional intraplate deformation. A pre-Mesozoic origin of this mantle fabric is also suggested by the higher annealing degree of the microstructures of the coarse-granular Borborema xenoliths relative to the Fernando de Noronha ones (Fig. 2), which record deformation frozen up in the oceanic lithosphere by plate cooling and hence that post-dates the opening of the Atlantic (Liu et al., 2019).

Some coarse-porphyroclastic lherzolites have lower equilibrium temperatures (≤ 800 °C) than most coarse-granular peridotites. This is not a sampling location effect, since both types of peridotites were sampled in Pico do Cabugi. The higher olivine intragranular misorientations and less equilibrated olivine and pyroxene grain shapes indicate less effective annealing, pointing to either slower annealing due to cooler temperatures or a more recent deformation event. In the first case, the deformation recorded by these xenoliths may also be associated with the Brasiliano event. In the second, these peridotite may record Cretaceous or even younger deformation preserved in the shallow lithospheric mantle. However, the studied xenolith suite exhibits no evidence of strong deformation under low temperature conditions. There are no xenoliths displaying mylonitic microstructures, with marked grain size reduction of olivine and strong elongation of olivine and orthopyroxene porphyroclasts, which are usually observed in extensional shear zones developed in peridotite massifs under low temperature conditions (≤ 1000 °C; e.g., Drury et al., 1991; Frets et al., 2014; Kaczmarek and Tommasi, 2011). Although annealing could have partially obliterated the olivine deformation microstructure, it cannot change the aspect ratios of the orthopyroxenes in a time scale of 100 Ma. Thus if the low temperature coarse-granular peridotites correspond to sections of the lithospheric mantle deformed during the Mesozoic, these are low strain zones and their olivine CPO and seismic anisotropy may still preserve orientations produced by the previous deformation episodes.

Based on the microstructures of the low equilibration temperature peridotites and on the seismic anisotropy data, we conclude therefore that the shallow sections of the lithospheric mantle of the Borborema province record essentially coupled crust and mantle deformation during the formation of the Borborema shear zone system in the Neoproterozoic. The present dataset has no evidence for extensive reworking of the shallow lithospheric mantle by the extensional deformation in the Cretaceous or during the Cenozoic uplift of the province. Yet, the absence of (annealed or not) low-temperature mylonites in the xenolith sampling does not imply that shear zones accommodating a Mesozoic extension did not form in the shallow lithospheric mantle of the Borborema Province, since our sampling is punctual and such a deformation would be by nature heterogeneous.

The coarse-porphyroclastic microstructures that characterize the lower part of the lithospheric mantle (equilibrium temperatures > 1000 °C) are more difficult to relate to a given tectonic episode. Partial melting conditions estimated for the Ceará-Mirim basalts suggest that the lithosphere-asthenosphere boundary was shallower in the Cretaceous than in the Cenozoic (cf. Fig. 10 and discussion Section 5.2). This would imply that the deep lithospheric mantle beneath Borborema might be composed by material accreted by cooling

since the Cretaceous. Comparison between the microstructures of these coarse-porphyroclastic peridotites with those of peridotite xenoliths from the nearby Fernando de Noronha (FN) archipelago, formed in response to Cenozoic volcanism onto 100–105 Ma old crust in the equatorial Atlantic (Liu et al., 2019) also favors a Mesozoic age for the deformation of these peridotites. Indeed, the olivine M2M and olivine and pyroxene shape factors of the Borborema peridotites overlap with the lower range of olivine M2M and shape factors, that is, with the most annealed microstructures of the FN peridotites (Fig. 2). The FN peridotites record an asthenospheric deformation, which has been frozen in the oceanic lithosphere by cooling and evolved by annealing since then (Liu et al., 2019). Their deformation is therefore younger than the opening of the Equatorial Atlantic. The similar to slightly stronger annealing degree of the coarse-porphyroclastic Macau peridotites suggests that the deformation that produced these microstructures in the deep section of the lithospheric mantle beneath the Borborema province might be related to the early stages of Cretaceous extension. Thus, although this event did not result in widespread deformation of the shallow levels of the lithospheric mantle, it might have reworked the base of the lithosphere (bottom-up lithospheric thinning?). Yet the high SKS delay times in station RCBR do not favor strong deviations in flow direction from NNE across the entire lithosphere-asthenosphere section, implying that either strains were small and did not change the Neoproterozoic CPO orientations or that flow directions during extension were at high angle to the extensional structures in the Cretaceous basins and to the Equatorial Atlantic spreading directions.

Finally, the very low annealing degree and high equilibration temperatures of the fine-grained porphyroclastic microstructures necessarily imply deformation close in time to the Cenozoic Macau volcanism. Based on the microstructural evidence for high stresses, but low finite strains for this deformation, we propose that it is related to the formation of the dykes that brought the Macau volcanics to the surface. The equilibration temperatures of the xenoliths imply a rather hot geotherm, leading to an 80-km thick lithosphere in the Cenozoic. This is consistent with melting depths inferred for the Macau basalts (Ngonge et al., 2016b). It is also coherent with the present-day thermal state of the lithospheric and sublithospheric mantle as imaged by geophysical data.

Dating the reactive melt percolation events is even more difficult than the deformation ones. The equilibrated microstructures and the coherent olivine and pyroxene CPOs in the coarse-granular peridotites undoubtedly point to a Brasiliano or older reactive melt percolation event. Coarse-porphyroclastic peridotites record younger melt percolation events, which in some cases predated or were synchronous to the main deformation recorded by the samples. However, in other cases, like in the coarse-porphyroclastic harzburgites, melt percolation post-dated the main deformation. Finally, the non-equilibrated chemical compositions at the sample scale observed in many samples, in particular the high-temperature coarse-porphyroclastic harzburgites, point to a last event of melt percolation that shortly predated the extraction of the peridotites. In summary, this peridotite suite recorded multiple reactive melt percolation events, probably well separated in time and related to the different magmatic episodes recorded in the crust.

6. Conclusion

Integrated analysis of microstructures, crystal preferred orientations, mineral chemical compositions, and equilibrium temperatures in a suite of 22 peridotite xenoliths reveals that the lithospheric mantle beneath the Northern Borborema Province preserves microstructures related to different deformation episodes since at least the Neoproterozoic. In all cases, olivine CPO points to deformation by dislocation creep with dominant activation of [100](010) slip system. However, the deformation microstructures were modified by variable degrees of annealing. The analysis of the extent of the annealing considering the equilibration temperatures allows rough ‘dating’ of the

deformation episodes and relating them to the major deformation events recorded in the crust. The well-annealed olivine microstructures and pyroxene shapes in coarse-granular peridotites equilibrated at ca. 900 °C indicate that the last deformation event that affected these peridotites is several hundreds of Ma old. In contrast, the fine-porphyroclastic peridotites, which have equilibrium temperatures ≥ 1200 °C, have suffered a high stress deformation, which shortly predated their extraction, probably related to the dykes that fed the Cenozoic volcanism. The coarse-porphyroclastic microstructures, which are observed both in the shallow and deep lithospheric mantle are more difficult to relate to a given tectonic episode. Yet comparison between the microstructures of these peridotites and those of peridotite xenoliths from nearby Fernando de Noronha island, which sample the oceanic mantle lithosphere of an old domain of the Equatorial Atlantic, suggest that the high-temperature coarse-porphyroclastic peridotites may record deformation related to the Cretaceous extension. Multiple reactive melt percolation events, probably well spaced in time, may also be inferred based on the microstructures, modal, and mineral compositions of the xenoliths.

Comparison of the computed seismic anisotropy of the lithospheric mantle based on the xenolith data to SKS splitting in nearby RCBR station supports that the strongest contribution of the lithospheric mantle to the measured anisotropy would correspond to a frozen strike-slip fabric parallel to the major NNE-NE Neoproterozoic shear zones in the region. A shallow lithospheric mantle fabric parallel to the Neoproterozoic shear zones is also suggested by anisotropic receiver functions (Lamarque and Julià, 2019). These observations corroborate the conclusion that the shallow lithospheric mantle in the Northern Borborema province still preserves a structure acquired by coupled crust-mantle deformation during the formation of the Borborema shear zone system in the Neoproterozoic. It also suggests that Cretaceous extension, which seems to be recorded in the deeper sections of the lithosphere, did not produce pervasive reworking of the shallow lithospheric mantle, pointing to ‘partial’ or total crust-mantle decoupling during this event. However, even if the entire lithospheric mantle has a frozen strike-slip fabric parallel to the major NNE-NE Neoproterozoic shear zones in the region, it can produce $< 1/3$ of the measured delay time of 1.9 s in station RCBR. Thus most of the measured SKS splitting in RCBR should record flow in the sublithospheric mantle, which also has a NNE orientation, not parallel to the APM, but consistent with predictions of mantle circulation models for this region.

Finally, equilibrium temperatures and petrological compositions of the xenoliths indicate a rather hot Cenozoic geotherm, implying a ca. 80 km thick lithosphere. This estimate is consistent with the melting conditions estimated for the formation of the Macau basalts (Ngonge et al., 2016b). It is also coherent with geophysical data that point to a present-day 80-km thick lithosphere (Heit et al., 2007) and hotter than average sublithospheric mantle beneath this region (French et al., 2013; Simões Neto et al., 2019).
