Abstract

The question of the rampant erosion of the shorelines rimming the Mekong River delta has assumed increasing importance over the last few years. Among issues pertinent to this question is how it is related to mangroves. Using high-resolution satellite images, we compared the width of the mangrove belt fringing the shoreline in 2012 to shoreline change (advance, retreat) between 2003 and 2012 for 3687 cross-shore transects, spaced 100 m apart, and thus covering nearly 370 km of delta shoreline bearing mangroves. The results show no significant relationships. We infer from this that, once erosion sets in following sustained deficient mud supply to the coast, the rate of shoreline change is independent of the width of the mangrove belt. Numerous studies have shown that: (1) mangroves promote coastal accretion where fine-grained sediment supply is adequate, (2) a large and healthy belt of fringing mangroves can efficiently protect a shoreline by inducing more efficient dissipation of wave energy than a narrower fringe, and (3) mangrove removal contributes to the aggravation of ongoing shoreline erosion. We fully concur, but draw attention to the fact that mangroves cannot accomplish their land-building and coastal protection roles under conditions of a failing sediment supply and prevailing erosion. Ignoring these overarching conditions implies that high expectations from mangroves in protecting and/or stabilizing the Mekong delta shoreline, and eroding shorelines elsewhere, will meet with disappointment. Among these false expectations are: (1) a large and healthy mangrove fringe is sufficient to stabilize the (eroding) shoreline, (2) a reduction in the width of a large mangrove fringe to the benefit of other activities, such as shrimp-farming, is not deleterious to the shoreline position, and (3) the effects of human-induced reductions in sediment supply to the coast can be offset by a large belt of fringing mangroves.

Keywords: Mangroves, Mekong River delta, shoreline erosion, coastal squeeze, sediment supply

1 **1. Introduction**

2 Mangroves are halophytic (tolerant to saline waters) coastal forests that develop at the interface
3 between muddy shores and mostly brackish waters. Mangroves are characteristic of many tropical and
4 subtropical coastlines between 32°N and 38°S (Brander et al., 2012). An ecosystem in its own right,
5 mangroves shelter various fauna, and the thriving and survival of which are totally dependent on healthy
6 mangroves. A wide and healthy belt of mangroves fringing the shoreline also plays a significant role in
7 contributing to coastal protection by dissipating waves under normal energetic ocean forcing conditions.
8 This protective role has been demonstrated in several studies conducted theoretically (Massel et al.,
9 1999), in the laboratory (Hashim and Catherine, 2013), and from field monitoring (Mazda et al., 1997;
10 Quartel et al., 2007; Barbier et al., 2008; Horstman et al., 2014), but also from geomorphological and
11 coastal management-oriented approaches (Anthony and Gratiot, 2012; Winterwerp et al., 2013; Phan et
12 al., 2015). The protective role of mangroves during the course of extreme climatic and tsunami events
13 and disasters has been underlined (e.g., Alongi, 2008; Gedan et al., 2011; Marois and Mitsch, 2015).
14 Mangroves are closely linked with their physical environment and contribute to land-building by trapping
15 sediment through their complex aerial root structure (e.g., Carlton, 1974; Kathiresan, 2003; Anthony,
16 2004; Corenblit et al., 2007; Kumara et al., 2010). By contributing to delta aggradation, mangroves
17 mitigate sea-level rise effects induced by climate change, which in turn are a threat to this ecosystem
18 (Gilman et al., 2007; McKee et al., 2007; Gedan et al., 2011; Woodroffe et al., 2016). Healthy mangroves
19 can trap more than 80% of incoming fine-grained sediment (Furukawa et al., 1997) and contribute to
20 sedimentation rates of the order of 1-8 mm/year, generally higher than local rates of mean sea-level rise
21 (Gilman et al., 2006; Gupta, 2009; Horstman et al., 2014).

22 On coasts characterized by mangroves, resilience to high-energy events such as tsunami or
23 repeated storms can be impaired where mangrove loss has been generated and sustained by human
24 activities. This can be envisaged through consideration of the concept of the tipping point, which
25 corresponds to a threshold value beyond which a system cannot return to its original dynamic equilibrium
26 (Kéfi et al., 2016). Tipping points occur where one or more of the driving processes go beyond a
27 threshold, resulting in destabilized dynamic feedback loops that link all processes together. This can be
28 expected where the sediment supply is drastically reduced (sediment trapping by dams, sand mining,
29 etc.), or where oceanic forcing is modified over a long period of time (18.6-year tidal cycles, ocean
30 oscillations, etc.). This is also the case where a mangrove fringe is reduced in width by coastal ‘squeeze’
31 or by deforestation (Lewis, 2005; Anthony and Gratiot, 2012). Coastal squeeze occurs where
32 anthropogenic modifications on the coast lead to a significant cross-shore reduction of coastal space
33 (Doody, 2004; Pontee, 2013; Torio and Chmura, 2013). A number of case studies have shown that
34 coastal squeeze can lead to coastal erosion, including in areas where mangroves occur (e.g.,
35 Heatherington and Bishop, 2012; Anthony and Gratiot, 2012; Winterwerp et al., 2013; van Wesenbeeck
36 et al., 2015; Toorman et al., 2018; Brunier et al., 2019). van Wesenbeeck et al. (2015) have highlighted
37 mangrove sensitivity to human pressures and the feedback effects resulting from conversion of mangrove
38 lands to intensive aquaculture that generates coastal erosion. This leads to a breakdown of the buffer

39 effect of the mangrove forest on wave energy and in promoting sediment trapping. This alteration can
40 encourage accelerated erosion (Mitra, 2013). In addition, in the case of aquaculture and agriculture, the
41 river channels commonly become disconnected from the natural floodplain to the benefit of farming,
42 which results in a significant reduction of sediment supply to the floodplain. A particularly overlooked
43 area in gauging the significance of mangroves is that of adequate sediment supply, an overarching
44 background factor without which the commonly considered 'land-building' role of mangroves cannot be
45 successful. Mangroves are limited producers of sediment (organic or authigenic production), whereas the
46 negative effects of the reduction of allogenic sediment supply by rivers caused by trapping by dam
47 reservoirs and by sand mining are often aggravated by accelerated subsidence and sea-level rise. Both
48 create accommodation space that then requires more sediment to maintain mangrove substrate elevations.

49 The Mekong delta in Viet Nam (Fig. 1), the third largest delta in the world (Coleman and Huh,
50 2004), has a particularly well-developed mangrove environment (Veettil et al., 2019). The delta makes up
51 for 12 % of the country's natural land and 19 % of its national population, and hosts a population of 20
52 million inhabitants (Mekong River Commission, 2010). The delta is crucial to the food security of
53 Southeast Asia, and provides 50% of Viet Nam's food (General Statistics Office of Viet Nam) and is part
54 of a river with the most concentrated fish biodiversity per unit area of any large river basin in the world,
55 with 454 fish species in the delta alone (Vidthayanon, 2008), and ranking second only to the Amazon in
56 overall biodiversity (WWF, 2012). As the country's largest agricultural production centre, the delta
57 region contributes half of Viet Nam's rice output, 65 percent of aquatic products and 70 percent of fruits.
58 It also accounts for 95 percent of the country's rice exports and 60 percent of total overseas shipment of
59 fish. Following the ravages of the Viet Nam War (1960-1972) on the delta's forests, these important
60 advantages have significantly impacted the mangroves of the delta, notably in the muddy southwestern
61 and Gulf of Thailand areas where large tracts have been removed to provide timber for charcoal and for
62 the construction industry, and to make place for shrimp farms and aquaculture (Phan and Hoang, 1993;
63 Christensen et al., 2008; Veettil et al., 2019). Several recent studies have also shown that erosion is
64 becoming increasingly rampant along much of the delta shoreline (Anthony et al., 2015; Besset et al.,
65 2016; Allison et al., 2017; Li et al., 2017), leading to the recurrent displacement of coastal populations
66 (Boateng, 2012) and increasing recourse to coastal protection structures, notably dykes (Albers and
67 Schmitt, 2015). Sea dykes are being increasingly built along parts of the muddy East Sea and Gulf of
68 Thailand coasts for protection from marine flooding and for shrimp farms, generating a process of
69 'mangrove squeeze' (Phan et al., 2015).

70
71 The erosion of the Mekong delta has been attributed to sediment depletion associated with three
72 main factors (Anthony et al., 2015): (1) potential trapping of sediment by the increasing number of dams
73 constructed in the Mekong catchment, (2) large-scale commercial sand mining in the river and delta
74 channels, and (3) accelerated subsidence due to groundwater pumping. With regards to the first two
75 factors, recent studies have documented a marked reduction in the sediment load of the Mekong River
76 reaching the delta from 160 Mt/yr in 1990 to 75 Mt/yr in 2014 (Koehnken, 2014), and maybe even down

77 to 40 ±20 Mt/yr currently (Piman and Shrestha, 2017; Ha et al., 2018). This reduction also generates
78 mechanisms of sediment redistribution by waves and currents that could explain exacerbated shoreline
79 erosion in places (Marchesiello et al., 2019). 38% of the Mekong delta region is at risk of being
80 underwater by the year 2100 ([https://en.vietnamplus.vn/forum-to-talk-climateresilient-development-in-](https://en.vietnamplus.vn/forum-to-talk-climateresilient-development-in-mekong-delta/145888.vnp)
81 [mekong-delta/145888.vnp](https://en.vietnamplus.vn/forum-to-talk-climateresilient-development-in-mekong-delta/145888.vnp)), with a large contribution to this from subsidence generated by massive
82 groundwater extraction (Minderhoud et al., 2017). Anthony et al. (2015) also suggested, however, that
83 marked alongshore variability in erosion rates may also be influenced by differences arising from the
84 presence and protective role of mangroves, or their absence which may enhance erosion. Mangrove loss
85 thus comes out as an additional factor in modulating erosion of the Mekong delta. Phan et al. (2015)
86 showed that dissipation of waves incident on the delta shoreline was not effective where mangroves had
87 been removed, especially in the case of infragravity waves which require a large mangrove cover several
88 hundred metres wide to be significantly attenuated, such that mangrove removal indeed contributed to
89 shoreline erosion. On the basis of 18 individual cross-shore profiles distributed along about 320 km of
90 deltaic coast from the mouths of the Mekong to Ca Mau Point (Fig. 1), Phan et al. (2015) showed a net
91 correlation between mangrove width and local erosion or accretion. Notwithstanding their limited
92 number of data points and the large error bars of these points, Phan et al. (2015) identified a minimum
93 critical width of 140 m for a stable mangrove fringe, and, above this minimum width, a capacity to
94 promote sedimentation. The authors considered that the larger the width of the mangrove fringe the more
95 efficient the attenuation of waves and currents will be, offering a successful environment for both
96 seedling establishment and sedimentation. Indeed, this relationship is in agreement with numerous
97 previous studies showing that the larger the mangrove width, the better the protection offered by
98 mangroves against waves (e.g., Barbier et al., 2008). However, this finding is pertinent to wave energy
99 being dissipated across a more or less broad mangrove belt, which is not quite the same thing as
100 mangrove protection against an ongoing erosion process. Furthermore, an environment for successful
101 mangrove seedling requires that substrate accretion levels are maintained by sustained sediment supply
102 (Balke et al., 2011).

103
104 The objective of this paper is to further test the relationship described by Phan et al. (2015) based
105 on the rationale that the shoreline change trends deduced from satellite images in recent studies may be
106 correlated with mangrove width identified on the same satellite images. We first compare mangrove
107 width and shoreline change over cross-shore profiles at the scale of the entire delta, then at the scale of
108 the three deltaic sectors commonly identified along the Mekong delta (e.g., Anthony et al., 2015): the
109 delta distributary mouths sector (0-280 km), the ‘East Coast’ (280-379 km) bordering the South Sea, and
110 the ‘West Coast’ in the Gulf of Thailand (379-564 km) (Fig. 1). Following this, we gauged the
111 relationship between mangroves and shoreline change in the delta.

112

113 2. Data and Methods

114 2.1 Remote-sensing data

115 Using a relevant cartographic frame (Projection UTM 48N), a baseline B was set about 1 km
116 offshore (Fig. 2) of the Mekong delta shoreline. This baseline was regular enough to: (i) smooth any
117 small-scale instabilities related to a non-rectilinear shoreline, and (ii) delineate large-scale geomorphic
118 features such as capes or bays. We then set up regularly spaced transects perpendicular to the baseline
119 and extending from offshore to 3 kilometres inland. Following this, we projected a set of 43 high-
120 resolution SPOT 5 level 3 ortho-rectified colour satellite images for January 2003 (2003) and December
121 2011/February 2012 (2012) at a scale of 1:10,000 within the cartographic frame. These images, initially
122 described in Anthony et al. (2015), cover the ≈ 500 km of delta shoreline. The SPOT 5 images are 5 m
123 pixel-resolution panchromatic images (spectral band within 0.48-0.71 μm) acquired in pairs
124 simultaneously with a half-pixel spatial shift. The resulting SPOT 5 Super-Mode images offer a final
125 resolution of 2.5 m appropriate for precisely locating the shorelines and the edges of the mangrove fringe.
126 This is the best theoretical spatial resolution for the study.

127 2.2. Extraction of shorelines and mangrove limits

128 There is no standardized definition of the shoreline (e.g., Boak and Turner, 2005; Ruggiero and
129 List, 2009) and this implies the choice of a yardstick, preferably one that can be re-used in successive
130 surveys, to identify a position of the land-water interface. Following extensive field observations
131 covering over 300 km of the Mekong delta's shoreline over the period 2011-2012, Anthony et al. (2015)
132 suggested the use of the seaward limit of vegetation as the shoreline. The brush/plantation fringe in
133 sectors of sandy coast characterized by beaches, and the mangrove fringe in the muddy sectors, were
134 adopted as good 'shoreline' markers. We used the shoreline digitized in Anthony et al. (2015) from the
135 2003 and 2012 images using the automatic digital shoreline analysis DSAS (Himmelstoss et al., 2018),
136 and traced 4155 new cross-shore transects, spaced 100 m alongshore. This alongshore spacing appeared
137 to provide the best compromise between precision and the overall length of analyzed delta shoreline (415
138 km). Phan et al. (2015) selected a set of only 18 transects to define the relationship between mangrove
139 width and shoreline change over the period 1989-2002. Our study is based on the systematic analysis of a
140 much larger set of transects but also concerns a more recent period marked by increasing erosion of the
141 delta (Anthony et al., 2015; Li et al., 2017). Transects through mangrove vegetation were retained as the
142 primary basis for our analysis. It may be noted that at least half of the transects used by Phan et al. (2015)
143 could not have concerned mangrove-bearing shorelines since they went through sandy (open beach-
144 foredune) portions of the river-mouth sector (see their Fig. 1B). 45% (113 km out of 250 km) of the
145 delta's shoreline is characterized by 'upland' brush-plantation vegetation associated with these beaches
146 and foredunes in the river-mouth sector (Anthony et al., 2015). We digitized the inland limit of the
147 mangrove fringe using the same procedure as Phan et al. (2015). This consisted in using dikes observed
148 on satellite images as this inland limit (Fig. 2).

149 Along each cross-shore transect superimposed on these images, we digitised the following curves:

150 • S_{2003} : the shoreline in 2003,

151 • S_{2012} : the shoreline in 2012,

152 • M_{inland} : the line defining the 2012 inland limit of vegetation up to the main dike,

153 • M_{shore} : the line defining the 2012 seaward limit of vegetation.

154 Since the issue at hand here is simply that of determining the relationship between the width of a
155 mangrove fringe at a time t with shoreline change over several years, we had a choice between the 2003
156 and 2012 satellite images. The results yielded by the two datasets are virtually identical (Supplementary
157 Material 1). We preferred, thus, the 2012 images which are of better quality than those of 2003,
158 especially for delimiting the landward vegetation fringe, and the comparison is coherent with that
159 adopted by Phan et al. (2015).

160 We extracted the positions of the four digitized lines at the intersection with each cross-shore
161 profile. Thus, in the cartographic frame, we obtained four sets of shorelines and limits of mangroves:
162 $(X_{2003}^i; Y_{2003}^i)_{i \in [1:N]}$, $(X_{2012}^i; Y_{2012}^i)_{i \in [1:N]}$, $(X_{inland}^i; Y_{inland}^i)_{i \in [1:N]}$, and $(X_{shore}^i; Y_{shore}^i)_{i \in [1:N]}$ where i
163 refers to a cross-shore profile and N is the total number of cross-shore profiles. In addition, we obtained
164 the set $(X_B^i; Y_B^i)_{i \in [1:N]}$ of node coordinates along the baseline from which each cross-shore transect
165 commences.

166 Using these five datasets, we determined the following distances to the baseline:

167 • the distance of the 2003 shoreline

168
$$S_{2003}^i = \sqrt{(X_{2003}^i - X_B^i)^2 + (Y_{2003}^i - Y_B^i)^2} \quad (1)$$

169 • the distance of the 2012 shoreline

170
$$S_{2012}^i = \sqrt{(X_{2012}^i - X_B^i)^2 + (Y_{2012}^i - Y_B^i)^2} \quad (2)$$

171 • the distance of the 2012 inland edge of the mangrove fringe

172
$$M_{inland}^i = \sqrt{(X_{inland}^i - X_B^i)^2 + (Y_{inland}^i - Y_B^i)^2} \quad (3)$$

173 • the distance of the 2012 seaward edge of the mangrove fringe

174
$$M_{shore}^i = \sqrt{(X_{shore}^i - X_B^i)^2 + (Y_{shore}^i - Y_B^i)^2} \quad (4)$$

175 We calculated the mean annual rate of shoreline change V_S^i at each cross shore transect i :

176
$$V_S^i = \frac{S_{2003}^i - S_{2012}^i}{\Delta T} \quad (5)$$

177 where ΔT is the time interval between the two consecutive SPOT 5 surveys (9 years). We also
 178 calculated the current width of the mangrove fringe W^i at each cross-shore transect i :

179
$$W^i = M_{inland}^i - M_{shore}^i \quad (6)$$

180 Following these procedures, we carried out analysis of possible relationships between V_S^i and W^i
 181 at various spatial scales, by considering various subsets of cross-shore transects. A few stretches of
 182 shoreline (less than 5% overall) could not be analyzed because of various technical problems such as
 183 cloud cover, thin (< 10 m wide) residual mangrove fringe, or where the edge of mangroves was not
 184 readily distinguishable on the images. Finally, taking into account these limitations, we obtained 3687
 185 relevant pairs of shoreline change (V^i) and mangrove width (W^i).

186

187 **2.3. Error margins and uncertainty**

188 Anthony et al. (2015) demonstrated that a good estimate of E_V , the mean uncertainty for V^i , is of
 189 the order of ± 5 m/yr for all of the cross-shore transects. In this paper, we needed to define the margin of
 190 error in the quantification of W^i . To do so, we considered E_p [m], the total error in the positioning of the
 191 points defining mangroves inland and the limits of the shore (Fletcher et al., 2003; Rooney et al., 2003;
 192 Hapke et al., 2006):

193
$$E_p = E_r^2 + E_g^2 + E_c^2 \quad (7)$$

194 The three mean squared errors are relative to: (i) E_r [m] the image resolution, (ii) E_g [m] the SPOT
 195 5 georeferencing, and (iii) E_c [m] the size of the cursor used to digitize the mangrove fringe line (which
 196 depends on the scale at which the image is plotted during digitizing). Fletcher et al. (2003), Rooney et al.
 197 (2003), and Hapke et al. (2006) considered tidal fluctuations as a possible alternative source of
 198 uncertainty in E_p . To handle this problem, we checked that the SPOT 5 images in 2012 were shot more
 199 or less at the same moment in the tidal cycle. Thus, this contribution remains very negligible and was not
 200 considered further in this study.

201 Practically, E_c was set to 2.8 m precisely for the study. E_g varied from 1.4 to 2.9 m. E_r was 2.5 m
 202 as explained above. As a consequence, we had a mean positioning uncertainty E_p ranging from 4.0 to 4.7
 203 m. We considered this margin of error as constant throughout for all the 3687 profiles. Finally, we
 204 calculated E_W [m] the mean uncertainty for the mangrove fringe widths W^i for all the transects as being
 205 the quadratic error of positioning at the inland and seaward limits of the mangrove fringe:

$$206 \quad E_W = \frac{1}{N} \sum \left(\sqrt{E_{inland}^2 + E_{shore}^2} \right) \quad (8)$$

207 where E_{inland} is the positioning error defined for the inland limit of the mangrove width and
 208 E_{shore} that of the seaward limit. As the SPOT 5 images are the same for seaward and inland limit
 209 digitizing, $E_{inland} = E_{shore}$, which meant that:

$$210 \quad E_W = \frac{\sqrt{2}}{N} \sum_1^N E_p \quad (9)$$

211

212 3. Results

213 The statistical comparison between shoreline change and coastal mangrove width is carried out at
 214 two scales: regional and local.

215 3.1 Regional scale (river-mouths/East Coast/West Coast)

216 When all 3687 transects are considered, there are no statistical correlations at the larger, regional
 217 scale (Fig. 4). 31% (≈ 80 km) of eroded shorelines are bordered by a mangrove width larger than the
 218 upper limit of a 500 m-wide mangrove fringe proposed by Phan et al. (2015) to ensure sediment trapping.
 219 Delimiting a threshold is difficult when all the data are taken into account without sorting. We therefore
 220 resorted to discretization and ranking of the results.

221 The results obtained thus show a decline in the number of cross-shore eroding transects as the
 222 width of the mangrove fringe increases (Fig. 4). In the delta distributary mouths, a decrease in the
 223 proportion of eroding transects in favour of that of prograding transects is observed, with mangrove
 224 width increasing until a threshold of 400 m. In this sector, only 8.5% (116 out of the 1370 profiles) of the
 225 shoreline shows a direct linear relationship between mangrove width and the rate of erosion/accretion.

226 Along the East and West Coasts, no trend comes out, the percentage of transects in erosion varying
 227 only slightly as a function of mangrove width (Fig. 4B). In fact, the number of erosional transects along
 228 the East Coast increases despite large mangrove widths, whereas the number of those in the mouths
 229 sector and the West Coast decrease (i.e. 0.6–1.2 km-wide mangrove). The results also show that the East

230 Coast is largely dominated by erosion (97% of black dots in Fig. 3), even though the width of the
231 mangrove belt exceeds 2 km in places.

232 3.2 Local scale (5 km-long transects)

233 To go further into the analysis, we divided the shoreline into longshore segments of 5 km (50
234 consecutive transects) (Fig. 5). At this scale, we integrated transects with non-mangrove vegetation at the
235 delta distributary mouths. Each line in the figure represents a coastal segment where a linear trend is
236 observed. Along the 482 km of shoreline analyzed (including 113 km of shoreline with ‘upland’ brush-
237 plantation vegetation), we identified only nine segments of deltaic shoreline, exclusively in the mouths
238 sector and the West Coast, showing a significant relationship ($r^2 > 0.75$, up to 1) between mangrove width
239 and shoreline change (Fig. 5). Each segment has an alongshore length ranging from 0.5 to 5 km (5 to 50
240 consecutive points separated 100 m alongshore are aligned in Fig. 3). These segments represent a
241 cumulative length of 37 km, i.e. $\approx 10\%$ of the total length of analyzed shoreline. Of this, 16.6 km
242 correspond to shoreline segments with non-mangrove vegetation.

243

244 4. Discussion

245 At the overall regional scale, our results reveal a pattern that is more complex than the simple
246 linear relationship proposed by Phan et al. (2015) between mangrove width and the status of the shoreline
247 in the Mekong delta. The results obtained in the present study, and based on a comprehensive analysis of
248 3687 pairs of shoreline change and mangrove width spaced 100 m (i.e., covering a total shoreline length
249 of 369 out of ca. 500 km of delta shoreline), show no statistically significant relationships, whatever the
250 scale considered (Figs. 3, 4, 5). This goes with the field observations of Anthony et al. (2015) who
251 reported active and quasi-continuous alongshore erosion of muddy mangrove-bearing bluffs along much
252 of the East and West Coasts in 2012. Two immediate inferences that come out of these findings are: (1)
253 that a large mangrove width is not necessarily tantamount to shoreline progradation in the Mekong delta;
254 (2) the overarching role of prevailing erosion which, where established, leads to sustained shoreline
255 retreat, whatever the width of the mangrove belt. There is no doubt that mangroves, by dissipating waves
256 and currents, can contribute actively to protection of a variably wide coastal fringe (which is not quite the
257 same thing as protection of the shoreline on which waves impinge), and can, especially, promote rapid
258 coastal accretion where fine-grained sediment supply is adequate, or delay, but not halt, coastal retreat,
259 where the sediment supply is inadequate. Our study shows, however, that for $\approx 90\%$ of the Mekong delta
260 shoreline, the relationship between mangroves and how the shoreline evolves needs to be carefully
261 considered in a context that takes into account antecedent and prevailing shoreline erosion or accretion.
262 These situations of erosion or accretion are, in turn, vested in the larger-scale control exerted by
263 alongshore adjustments between net sediment supply or availability, wave and current energy, and
264 sediment redistribution by waves and currents (Anthony et al., 2015; Marchesiello et al., 2019). Ignoring

265 these basic aspects may imply that high expectations from mangroves could be met with disappointment.
266 This can have important shoreline management implications because of the following wrong deductions:
267 (1) a large mangrove fringe is enough to stabilize a (eroding) shoreline, (2) some reduction of the
268 mangrove width to the benefit of other activities such as shrimp-farming is not deleterious, and (3) the
269 effects of human-induced reductions in sediment supply to the coast can be offset by mangroves.

270 The foregoing points simply warn that the efficiency of mangroves in assuring shoreline stability
271 needs to be viewed in the light of the established (decadal) shoreline trend, which, in turn, is determined
272 by sediment supply and hydrodynamic conditions. The protective capacity of mangroves can be
273 particularly impaired where sediment supply is in strong or persistent deficit, fine examples being the
274 mangrove-rich Guianas coast between the Amazon and Orinoco river mouths, the world's longest muddy
275 coast (Anthony and Gratiot, 2012). Here, so-called decadal to multi-decadal 'inter-bank' phases of
276 relative mud scarcity separating mud-rich 'bank' phases (discrete mud banks migrating alongshore from
277 the mouths of the Amazon are separated by inter-bank zones of erosion) can be characterized by rates of
278 shoreline erosion that can exceed 150 m/year notwithstanding the presence of dense mangrove forests up
279 to 30 m high and forming stands several km-wide (Brunier et al., 2019).

280 The width of the energy-dissipating mangrove fringe alone does not play a determining role,
281 neither in the context of erosive oceanic forcing, nor in the context of decreasing sediment supply to the
282 delta. This reflects a tipping-point effect wherein once sediment supply to the coast is in chronic deficit (a
283 deficit aggravated by delta-plain trapping to compensate for accelerated subsidence), the vertical growth
284 of shorefront mudflats is no longer assured. Mangrove colonization can be precluded where shorefront
285 mudflat elevations are below a tidal level threshold to enable seedling establishment (Proisy et al., 2009;
286 Balke et al., 2011, 2013). Shorefront substrate elevations in the Mekong delta have not been monitored,
287 but these unfavourable conditions for mangroves are likely exacerbated by: (1) narrowing of the
288 mangrove fringe which entails less wave dissipation and therefore decrease in turbulence dissipation and
289 flocculation (Gratiot et al., 2017); and (2) the increasing number of aquaculture farms and dykes to
290 protect rice farms, limiting the tidal prism with negative effects on sediment trapping (Li et al., 2017). At
291 the local scale of a few km, increasing mangrove width can be correlated with shoreline change, as at km
292 ≈ 455 in the southern extremity of the delta, near Ca Mau point (Fig. 1), where there appears to be
293 convergence of suspended mud (Marchesiello et al., 2019). Hence, the pertinence of a comparative
294 analysis at different scales (local/individual transects, alongshore segments, delta mass as a whole
295 representing the entire river basin).

296 Reflections on coastal management and coastal protection measures adapted to the Mekong delta
297 imply acquiring a good grasp of the resilience of the delta's mangroves. Efforts aimed jointly at
298 maintaining and preserving, rather than further destroying, mangroves (Jhaveri and Nguyen, 2018;
299 Veettil et al., 2019), and in assuring sustained sediment supply to the delta shores, will also be required in
300 the years to come.

301

302 **5. Conclusions**

303 1. The width of the mangrove fringe rimming 369 km ($\approx 90\%$) of the Mekong delta shoreline, and
304 shoreline change between 2003 and 2012, were determined for 3687 cross-shore transects spaced 100 m
305 apart from a comparison of high-resolution satellite images. The results show that 68% of the delta
306 shoreline is undergoing erosion and 91% of the eroding shoreline is characterized by mangroves.

307 2. Statistical relationships between shoreline change and mangrove width were determined: (a) at
308 the scale of the entire dataset of 3687 transects, (b) at the scale of the three sectors composing the delta
309 shoreline: the delta distributary mouths, dominantly characterized by sandy beach-dune shorelines, and
310 which was therefore largely excluded from this analysis, and the muddy East and West coasts, hitherto
311 rich in mangroves, and, (c) at a more local level comprised of transects over shoreline segments of 5 km.

312 3. The results show no significant trend, whatever the level considered. This finding differs from
313 that of Phan et al. (2015) who depicted, on the basis of only 18 data points, a linear relationship between
314 reduced mangrove width and coastal erosion. A linear relationship was observed in a very few sectors
315 accounting for less than 5.5% of the entire delta shoreline.

316 4. Phan et al. (2015) identified a minimum critical width of 140 m for a stable mangrove fringe, and
317 above this width, a capacity for mangroves to promote sedimentation. Although a wide and healthy
318 mangrove fringe is desirable, the 140 m-width recommended by Phan et al. (2015) is not a scientifically
319 defensible width.

320 5. Our results indicate that the role of mangroves in coastal protection needs to be carefully
321 considered in a context that takes into account antecedent prevailing shoreline erosion or accretion vested
322 in the larger-scale alongshore adjustments between net sediment supply and the ambient coastal
323 dynamics driven by waves and currents.

324 6. Beyond a certain threshold of deficient mud supply, and under maintained ambient
325 hydrodynamic conditions, mangroves, whatever their width, can no longer assure shoreline advance or
326 even stability, although they contribute to the attenuation of erosion by waves and currents.

327 7. Although erosion of mangrove-colonized shorelines results from natural morpho-sedimentary
328 adjustments driven by sediment supply and hydrodynamic forcing, mangroves can contribute actively to
329 coastal protection even under a context of shoreline erosion. Mangrove removal contributes, thus, to the
330 aggravation of shoreline erosion.

331 8. Reflections on coastal protection in the Mekong delta require not only a good knowledge of the
332 resilience of mangroves, efforts aimed at preserving them, but also understanding the large-scale

333 processes (source-to-sink sediment supply, oceanic forcing, climate change) that assure sustained
334 sediment supply to the delta shores, building and maintaining the delta in a dynamic equilibrium.

514 **FIGURE CAPTIONS**

515

516 Figure 1. Map of the Mekong River delta showing shoreline change between 2003 and 2012 (from
517 Anthony et al., 2015) in the three shoreline sectors: the sand-dominated delta distributary mouths, and the
518 muddy East and West Coasts. Small rectangle on the East coast shoreline shows location of shoreline
519 examples depicted in Fig. 2.

520 Figure 2. Examples of shorelines and positioning of the mangrove edge for digitization (see location in
521 Fig. 1).

522 Figure 3. Graph showing the variation of Mekong delta shoreline change rates from 2003 to 2012 with
523 mangrove width in 2012 (each dot corresponds to a transect), and discrimination of the three shoreline
524 sectors (red dots for delta distributary mouths, black dots for East Coast, blue dots for West Coast). The
525 six histograms show the frequency distribution for each sector with regards to mangrove width (left), and
526 shoreline change (right).

527 Figure 4. Graphs showing the number (top) and the percentage (bottom) of transects in erosion among all
528 transects in the different classes of 0.1 km mangrove-width range.

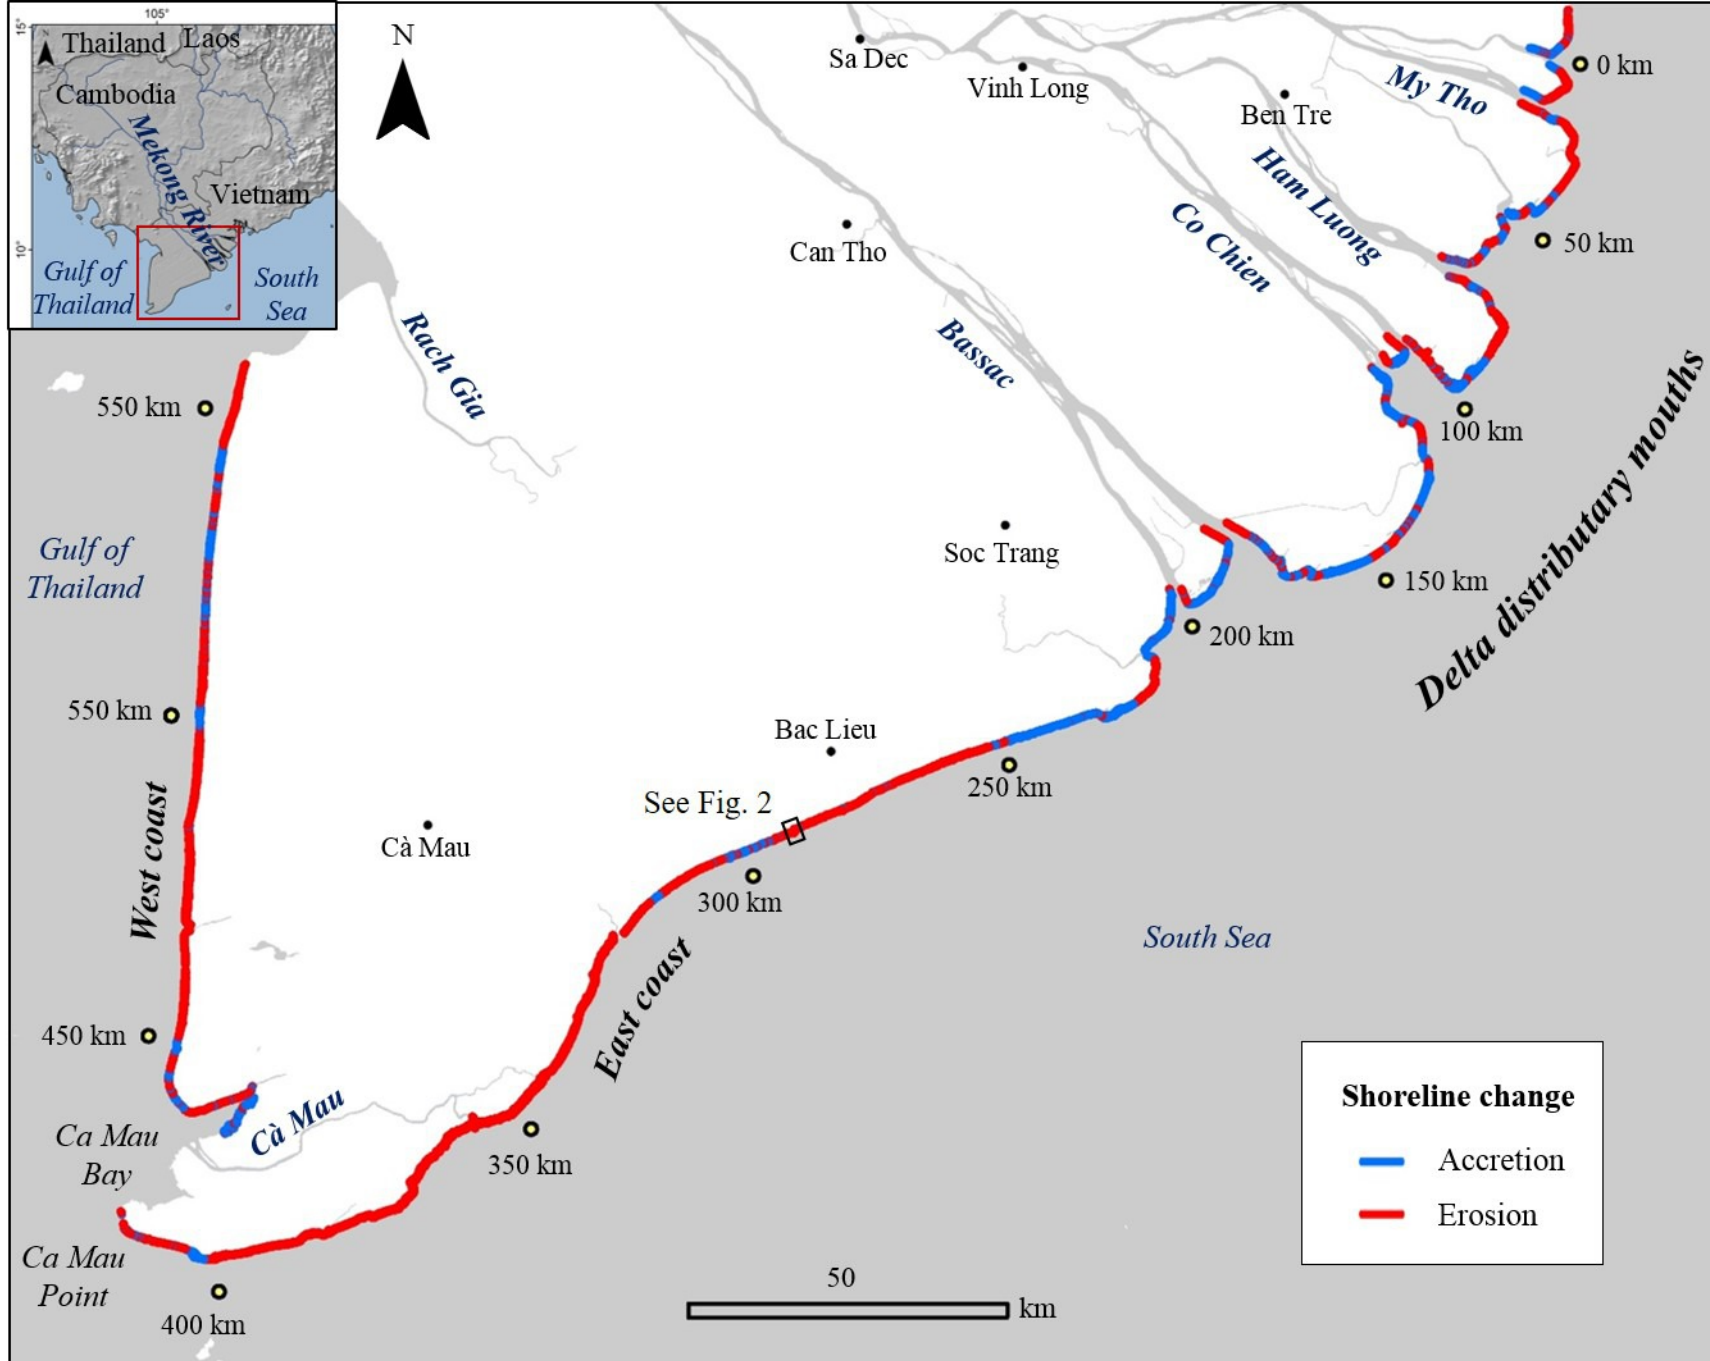

529 Figure 5. Locations of the 10% of shoreline sectors exhibiting a significant correlation between width of
530 fringing vegetation and erosion/accretion. Of this, mangroves represent less than 5%.

531

532 Supplementary material

533 Comparison of the relationship between mangrove width and shoreline change based on the 2003 (a) and
534 2012 (b) satellite images.
