Abstract

Viewing calcium hydrazinidoborane $\text{Ca}(\text{N}_2\text{H}_3\text{BH}_3)_2$ (9.3 wt% H) as a potential hydrogen storage material, we long sought to synthesize it by solid-solid reaction of calcium hydride CaH_2 and hydrazine borane $\text{N}_2\text{H}_4\text{BH}_3$. However, it was elusive because of unsuitable experimental conditions. In situ synchrotron thermodiffraction helped us to identify the key role played by the temperature in the formation of the new phase. From 45°C, new diffraction peaks appear, and the DSC analysis shows an exothermic signal. Thermal activation is thus required to make solid-state CaH_2 react with melted (liquid-state) $\text{N}_2\text{H}_4\text{BH}_3$. The XRD pattern can be indexed using a mixture of two phases: (i) unreacted CaH_2 as a minor phase (29 wt%) and (ii) the hitherto elusive $\text{Ca}(\text{N}_2\text{H}_3\text{BH}_3)_2$ (71 wt%). The as-formed $\text{Ca}(\text{N}_2\text{H}_3\text{BH}_3)_2$ crystallizes in a monoclinic *Ic* (No. 9) unit cell where the intermolecular interactions form chains (layers) along the *a* axis, resulting in intra-chain and inter-chain $\text{Ca}\cdots\text{Ca}$ distances as short as 4.39 and 7.04 Å respectively. Beyond 90°C, $\text{Ca}(\text{N}_2\text{H}_3\text{BH}_3)_2$ decomposes, as evidenced by the diffraction peaks fading, an exothermic signal revealed by DSC, a weight loss (5.3 wt% at 200°C) observed by TGA, and a gas release (H_2 , and some N_2 , NH_3 , N_2H_4) monitored by MS. The as-formed thermolytic residue is amorphous and of complex polymeric composition. These results and the next challenges, are discussed herein.

Keywords

Calcium hydrazinidoborane; Dehydrogenation; Hydrazine borane; Hydrogen storage.

1. Introduction

In the field of chemical hydrogen storage, B-N-H materials emerged as promising candidates. They draw their strength from high gravimetric hydrogen densities as well as the concomitant existence of B–H^{δ-} and N–H^{δ+} bonds resulting in heteropolar dihydrogen B–H^{δ-}...H^{δ+}–N interactions which drive their solid state at ambient conditions and their ability to release H₂ at relatively mild conditions. A typical representative of B-N-H materials is ammonia borane NH₃BH₃ (AB), composed of 19.5 wt% of hydrogen [1-4]. In pristine state, AB decomposes more than it dehydrogenates, and is not suitable for the targeted application [5-8]. A number of derivatives has been further developed. The strategy is to substitute one H^{δ+} of the NH₃ group of AB by a cation to form alkali and alkaline-earth amidoboranes M(NH₂BH₃)_n, with Mⁿ⁺ being e.g. Li⁺, Na⁺, Mg²⁺, or Ca²⁺ [9,10]. The idea is to destabilize the anionic entity [NH₂BH₃]⁻ so that the ionic solid M(NH₂BH₃)_n releases pure H₂ at temperatures lower than those required for AB decomposition. A typical example is sodium amidoborane NaNH₂BH₃ (9.5 wt% H) that starts to dehydrogenate at about 50°C and is able to release 7.5 wt% H (2 equiv H₂) up to 200°C [11].

Another representative of B-N-H materials is hydrazine borane N₂H₄BH₃ (HB), composed of 15.4 wt% of hydrogen [12]. HB is a derivative of AB, the NH₃ of which being substituted by N₂H₄. Yet, HB, in pristine state, is not suitable for hydrogen storage because, under heating, it releases N₂H₄ together with H₂, and it generates a shock-sensitive solid when heated above 300°C [13]. Alkali hydrazinidoboranes NH₂NH(M)BH₃ (or MN₂H₃BH₃; denoted MHB) were synthesized by reaction of HB with an alkali hydride MH in such a way that one H^{δ+} of the middle NH₂ was substituted by M⁺ [14]:

MHB is an ionic solid [15]. Compared to HB, the B–H and N–H bonds of MHB are weaker, which results in more attractive dehydrogenation properties [16]. To date, four MHBs have been successfully synthesized.

The first example of MHB is the polymorphic LiN₂H₃BH₃ (denoted LiHB), prepared by ball-milling equimolar amounts of HB and LiH [17,18]. The low-temperature β phase (orthorhombic, s.g. *Pbca*) transforms into the metastable high-temperature α phase (monoclinic, s.g. *P2₁/c*) at around 90°C [19]. LiHB is able to release about 2.5 equiv H₂ when heated up to 150°C (i.e. 9.9

wt% H released, out of a gravimetric hydrogen density of 11.7 wt% H). The second example is $\text{NaN}_2\text{H}_3\text{BH}_3$ (NaHB; monoclinic, s.g. $P2_1/n$) [20]. NaHB is prepared at a temperature below -30°C because the reaction of HB with NaH is exothermic ($-27.8 \text{ kJ mol}^{-1}$) [21]. NaHB is less stable than LiHB: it releases H_2 from about 60°C , with about 2.6 equiv H_2 generated up to 150°C (i.e. 7.6 wt% H released, out of a gravimetric hydrogen density of 8.9 wt% H). The third example is $\text{KN}_2\text{H}_3\text{BH}_3$ (KHB; monoclinic, s.g. $P2_1$). It is synthesized in high pressure vessel and tetrahydrofuran [22], since the solid state reaction between HB and KH is violent ($-70.2 \text{ kJ mol}^{-1}$) [21]. KHB, less stable than the previous hydrazinidoboranes, starts to dehydrogenate below 50°C and, cumulatively, about 2.5 equiv H_2 are released up to 193°C (i.e. 6 wt% H released, out of a gravimetric hydrogen density of 7.2 wt% H). The fourth and last example is $\text{RbN}_2\text{H}_3\text{BH}_3$ (monoclinic, s.g. $P2_1$) [23]. Its dehydrogenation properties are favorably compared to those of LiHB. However, with a gravimetric hydrogen density of 4.65 wt% H and a very low terrestrial abundance of the element Rb, the potential of RbHB as hydrogen carrier appears to be rather limited.

To date, alkaline-earth hydrazinidoboranes $\text{M}(\text{N}_2\text{H}_3\text{BH}_3)_2$ (denoted $\text{M}(\text{HB})_2$, with $\text{M}^{2+} = \text{e.g. Mg}^{2+}, \text{Ca}^{2+}$) have not been properly considered and really investigated. Advantageously, they carry more hydrogen than NaHB (8.9 wt% H) and KH (7.2 wt% H) do; for instance, the theoretical gravimetric hydrogen densities of $\text{Mg}(\text{HB})_2$ and $\text{Ca}(\text{HB})_2$ are calculated to be 10.6 and 9.3 wt% H respectively. Another attractive feature is that calcium is, on earth, the most abundant element of the periodic table s block. One has to mention one study that reports the possible synthesis of $\text{Ca}(\text{HB})_2$ through an X-ray diffraction pattern that has not been refined and solved [17]. In a previous work [21], we tried to get such a $\text{Ca}(\text{HB})_2$ derivative by ball milling one equivalent of CaH_2 and 2 equivalents of HB at different milling conditions. However, all of our attempts failed. Soft ball milling conditions (e.g. 200 rpm for 10 min) resulted in binary mixtures of unreacted starting materials whereas harsher conditions (e.g. 450 rpm for 30 min) led to decomposition of HB into an amorphous polymeric solid. Consequently, we integrated another variable, the temperature. We focused our efforts in following the temperature-dependent evolution of the binary mixture $\text{CaH}_2\text{-2HB}$ by synchrotron X-ray thermodiffraction and differential scanning calorimetry. Our approach met with the successful synthesis of the first representative of alkaline-earth hydrazinidoboranes, i.e. calcium hydrazinidoborane $\text{Ca}(\text{N}_2\text{H}_3\text{BH}_3)_2$ (denoted $\text{Ca}(\text{HB})_2$), as described below. $\text{Ca}(\text{HB})_2$ was fully characterized by X-

ray diffraction, magic-angle spinning nuclear magnetic resonance spectroscopy, and Fourier transform infrared spectroscopy, and its dehydrogenation properties were followed by thermogravimetric analysis coupled to mass spectrometry.

2. Materials and methods

2.1. Materials

Hydrazine borane $\text{N}_2\text{H}_4\text{BH}_3$ (HB) was synthesized according to a protocol we previously optimized [13]. Calcium hydride CaH_2 (98%) purchased from Alfa Aesar was used as received. Both chemicals were stored and systematically handled in an argon-filled glove box (MBraun M200B, with $\text{O}_2 < 0.1$ ppm and $\text{H}_2\text{O} < 0.1$ ppm).

2.2. Preliminary comment

In the present project, we first attempted to synthesize $\text{Ca}(\text{HB})_2$ via a wet chemistry approach. Anhydrous tetrahydrofuran (THF; $\geq 99.9\%$; Sigma-Aldrich) was used. Under argon atmosphere (i.e. in the glove box) and at room temperature, 50 mg of HB (1.09 mmol) was dissolved in 10 mL of THF. In parallel, 23 mg of CaH_2 (0.546 mmol) was dispersed in 10 mL of THF. The borane solution was slowly added to the hydride dispersion. The mixture was allowed to age for 48 h under stirring. After solvent extraction, a solid consisting of unreacted HB and CaH_2 was recovered. This synthesis approach was thus abandoned, and we returned to our solid-solid reaction approach.

2.3. Temperature-dependent evolution of CaH_2 -2HB

The synthetic conditions for $\text{Ca}(\text{HB})_2$ were defined as follows. Under argon atmosphere, 275 mg of CaH_2 (6.5 mmol) and 600 mg of HB (13 mmol) were put in a stainless steel jar of 50 mL (containing 12 g of stainless steel balls) and mixed at 200 rpm for 10 min (Retsch PM 100 planetary mill). The resulting mixture, denoted **1**, was recovered to be stored under argon atmosphere. In another argon-filled glove box (MBraun Unilab, $\text{O}_2 < 0.1$ ppm and $\text{H}_2\text{O} < 0.1$ ppm), **1** was loaded into a glass capillary of 0.5 mm diameter. The capillary was sealed to prevent the sample from air and moisture. **1** was analyzed by X-ray thermodiffractometry using synchrotron radiation (Swiss Norwegian Beam Line SNBL BM01A, at European Synchrotron

Facility ESRF, Grenoble, France). The diffraction patterns were collected using a monochromatic beam and a PILATUS 2M detector. NIST standard LaB₆ was used for the calibration of all the parameters of the detector, the sample-detector distance (343.71 mm), and the wavelength of 0.70814 Å. The temperature change was controlled with an Oxford Cryostream 700+ allowing working over the range of temperature 19-100°C. The diffraction patterns were recorded simultaneously using a rotation of the capillary of 60° min⁻¹. In parallel, **1** was analyzed by differential scanning calorimetry (DSC; Q600, TA Instruments). The sample was heated from 0 to 75°C at 1°C min⁻¹, and then it was cooled down to 0°C at the same rate.

On the basis of the aforementioned thermodiffraction and DSC experiments, **2** (in fact a Ca(HB)₂-rich sample) was synthesized from **1**. Typically, **1** was loaded in a stainless reactor under argon atmosphere (in the glove box) and then sealed. The sample was heated up to 62°C at 1°C min⁻¹, kept at this temperature for 50 min, and quickly cooled down (by immersing the reactor in a tap water bath). The as-formed **2** was recovered and stored in the argon-filled glove box.

2.4. Characterization of Ca(HB)₂

Two XRD patterns among those collected were selected to be solved and indexed. The first pattern was that obtained at 19°C for **1** and consists in a mixture of CaH₂ and HB. It was refined using the Rietveld method to confirm the proportion of the two phases (cf. SI). The second pattern was the one collected at 62°C; it belongs to **2** that was found to consist in a mixture of Ca(HB)₂ and CaH₂. The unit cell parameters of Ca(HB)₂ were determined using DICVOL06 [24]. Starting from the determined parameters, the structural model of Ca(HB)₂ was obtained by using FOX [25]. The as-obtained model was refined using the JANA2006 software package [26]. The Rietveld refinement was carried out considering the two phases, Ca(HB)₂ and CaH₂, while for Ca(HB)₂ the fragments N–N–B were considered as being two different molecular fragments and as being rigid. The Rietveld refinement was carried out using a Pseudo-Voigt peak shape with a cut-off of 12 for the two phases. Considering the quality of the diffraction pattern, the isotropic thermal parameters (B_{iso}) were constrained to be identical for the same atom type in the unit cell. The locations of the H atoms linked to the N and B atoms were determined by performing a geometry constrained optimization of the structure (Ca, B and N atoms fixed in their initial positions) at the force-field level. All atoms of the system were represented as Lennard-Jones

charged sites with LJ parameters taken from the UFF force field [27] while the charges were calculated using the QeQ [28] method. In addition, the uncertainties of the atomic coordinates for the H atoms are not reported here because they were not refined.

2 was analyzed by magic-angle spinning nuclear magnetic resonance (MAS NMR) spectroscopy on the nuclei ^{11}B (Varian VNMR400; 128.37 MHz; 20000 rpm) and ^{43}Ca (Varian VNMR600; 40.37 MHz; 20000 rpm). To this end, **2** was loaded in the NMR rotor in the glove box. The rotor was afterwards put in an argon-filled vial (to prevent the sample from air and moisture) and transferred to the spectrometer localized in another building. The NMR analyses were performed at -10°C . **2** was also analyzed by Fourier transform infrared spectroscopy (FTIR; IS50 Thermo Fisher Scientific). The thermal behavior of **2** was studied by thermogravimetric (TG) analysis (Netzsch STA 449 F1 Jupiter) coupled to mass spectrometry (MS; Netzsch QMS 403D Aëolos Quadro) and by differential scanning calorimetry (DSC; Q600, TA Instruments). The heating rate was 1°C min^{-1} and the analyses were performed up to 300°C .

The thermolytic residue, denoted **3**, forming upon the decomposition of **2** at 200°C was prepared in high amount for analysis. Typically, **2** was loaded in a stainless reactor under argon atmosphere and sealed. It was heated up to 200°C at 1°C min^{-1} . Then it was allowed to cool down. The as-obtained **3** (recovered in the argon-filled glove box) was analyzed by powder X-ray diffraction (XRD; PANalytical X'Pert Multipurpose diffractometer equipped with an X'Celerator detector; Cu $K\alpha_1/\alpha_2$ radiation, $\lambda = 1.5418 \text{ \AA}$, 45 kV, 30 mA). The XRD pattern was collected using Bragg-Brentano geometry on a spinning zero background sample holder loaded in the glove box. The powder was protected using a Kapton foil stuck onto the sample holder with Apiezon grease (H quality) to prevent any air and moisture contamination. **3** was also analyzed by ^{11}B MAS NMR and FTIR spectroscopy.

3. Results and discussion

3.1. Synthesis of $\text{Ca}(\text{HB})_2$

Though the coveted $\text{Ca}(\text{HB})_2$ was elusive in our previous attempts [21], the TG analysis results of the binary mixture $\text{CaH}_2\text{-2HB}$ opened up a new possibility. An interesting feature was the

evolution of some H₂ starting from about 60°C, which was interpreted as a possible reaction of CaH₂ with melted HB, in some extent, such as:

The key to synthesize Ca(HB)₂ appeared to be the temperature. Then, our further efforts, through the present work, focused on the use of in situ synchrotron X-ray thermodiffraction to validate our assumption and to find the temperature at which the sought phase Ca(HB)₂ could be obtained.

We prepared a mixture of one equivalent of CaH₂ and two equivalents of HB, ball-milled at 200 rpm for 10 min under argon atmosphere. The as-obtained homogeneous mixture, denoted **1**, was heated at 1°C min⁻¹, starting from 19°C. The temperature evolution of **1** was analyzed by thermodiffraction up to 100°C (Figure 1 and S1). The thermodiffraction data were analyzed in conjunction with the DSC results (collected over the temperature range 0-75°C) (Figure 2). Below 45°C, the diffraction peaks can be all assigned to the CaH₂ and HB phases. For example, the XRD pattern collected at 19°C was refined using the Rietveld method (Figures 3 and S2, Table S1). The unit cell parameters and atomic positions for the two phases, i.e. HB and CaH₂, were found to be in good agreement with those published previously [13,29]. The relative amounts of the HB and CaH₂ solids obtained by the refinement of the powder XRD data were 27.9(5) and 72.1(2) wt%, leading to a molar ratio of 2.36.

Beyond 45°C, a baseline deviation of the heat flow is observed, suggesting an exothermic reaction. Concomitantly, new diffraction peaks appear, for example between 4 and 10°, and they grow with the increase of the temperature. Their apparition is correlated with the decrease of the intensity of the peaks of both CaH₂ and HB. In other words, a new phase, denoted **2**, is forming.

Figure 1. Sequential plot of the diffraction patterns obtained from **1** (the mixture of 1 equiv CaH_2 and 2 equiv HB) within the temperature range 19-100°C. The new phase is $Ca(HB)_2$.

Figure 2. DSC analysis of **1** upon heating up to 75°C and then cooling down to 0°C (heating rate of $1^{\circ}C min^{-1}$). The temperature ranges of the samples **1** and **2** are shown.

Figure 3. X-ray diffraction patterns of **1** collected at 19°C and 62°C. The main peaks belonging to CaH₂ (vertical dashed grey lines) and HB (symbol ◆) are shown (indexed pattern shown by Figure S2). The main peaks due to the new phase Ca(HB)₂ are indicated by the symbol ♥ (indexed pattern shown by Figure S3).

Above 55°C, the aforementioned exothermic event is compensated by an endothermic event that is typical of HB melting, but the exothermic signal gets rapidly over the endothermic one. Under cooling from 75°C down to 0°C, neither exothermic signal nor endothermic one is seen, bearing out the formation of the new phase. The key to synthesize Ca(HB)₂ seems to be the temperature, more precisely it seems to be HB in liquid state (leading to increased entropy factor) that is more likely to react with solid-state CaH₂. Peaks due to a small amount of unreacted CaH₂ can be seen above 55°C, which indicates that **2** would be a mixture of the new solid as the main phase (i.e. Ca(HB)₂) and of some CaH₂. Similar phase-rich solids were reported for the amidoborane counterpart Ca(NH₂BH₃)₂ that was prepared by ball-milling [30,31]. An additional experiment using Beyond 97°C, the diffraction peaks of **2** cannot be observed anymore, suggesting decomposition.

3.2. Crystal structure of Ca(HB)₂

The XRD pattern corresponding to the maximum intensity of **2** (i.e. that collected at 62°C) was successfully indexed using a mixture of two phases (Figures 3 and S3). The first phase is CaH₂, indexed as an orthorhombic *Pnma* (No. 62) unit cell [29]. The second one is Ca(HB)₂, indexed as a monoclinic *Ic* (No. 9) unit cell. The relative amounts of these two crystalline phases are 29.0(7)

and 71.0(3) wt%, respectively, as obtained by the refinement of the XRD pattern. The structure parameters corresponding to $\text{Ca}(\text{HB})_2$ (as well as those of the remaining CaH_2) are summarized in [Table 1](#).

The HB derivatives show the same lattice system, i.e. monoclinic, but $\text{Ca}(\text{HB})_2$ shows a different cell (s.g. Ic versus $P2_1/n$ for NaHB [20]). As a derivative of AB, $\text{Ca}(\text{NH}_2\text{BH}_3)_2$ shows a different monoclinic cell (s.g. $C2$ (No. 5)) [30]. Besides it shows a smaller cell volume per formula unit (138.5 \AA^3) compared to that of $\text{Ca}(\text{HB})_2$ (244.8 \AA^3); this is consistent with the larger size of the anion $[\text{N}_2\text{H}_3\text{BH}_3]^-$. The volume per formula unit of HB is also smaller with 80.2 \AA^3 [13]; this is consistent with the presence of the bulkier cation Ca^{2+} in $\text{Ca}(\text{HB})_2$.

According to the derived crystal structure of $\text{Ca}(\text{HB})_2$ ([Figures 4 and 5](#)), the intermolecular interactions form chains (layers) along the a axis. The $\text{Ca}\cdots\text{Ca}$ distance along the a axis (intra-chain) is the shortest one, with 4.39 \AA , whereas the inter-chain $\text{Ca}\cdots\text{Ca}$ distance is 7.04 \AA . The shortest $\text{Ca}\cdots\text{N}$ distance is 2.53 \AA , which is comparable to that in $\text{Ca}(\text{NH}_2)_2$ ($2.44\text{-}2.57 \text{ \AA}$) [32] and is slightly longer than the shortest distance in $\text{Ca}(\text{NH}_2\text{BH}_3)_2$ (2.47 \AA) [30]. The shortest $\text{Ca}\cdots\text{B}$ distance is 3.38 \AA , whereas distances of $2.87\text{-}3.03$ and $2.89\text{-}2.96 \text{ \AA}$ were reported for $\text{Ca}(\text{NH}_2\text{BH}_3)_2$ [30] and $\text{Ca}(\text{BH}_4)_2$ [33] respectively. The $\text{Ca}\cdots\text{H}\text{-B}$ and $\text{Ca}\cdots\text{H}\text{-N}$ distances resulting from the geometry optimization are between 2.33 and 2.43 \AA . With respect to the two directly binding anions, the distances of the N–N bonds from the Rietveld refinement are 1.38 and 1.40 \AA . They are comparable to the distance observed for HB (1.41 \AA) [13], but shorter compared to the MHBs ($\alpha\text{-LiHB}$ 1.47 \AA [17]; $\beta\text{-LiHB}$ 1.50 \AA [18]; NaHB 1.46 \AA [19]; KHB 1.47 \AA [22]; RbHB 1.43 \AA [23]). The B–N bonds have lengths of 1.53 and 1.57 \AA . This is consistent with the bond lengths in $\text{Ca}(\text{NH}_2\text{BH}_3)_2$ (1.55 \AA) [30] and in the MHBs ($1.54\text{-}1.55 \text{ \AA}$) [17,18,19,22,23]. They are all slightly shorter than the B–N bond of HB (1.59 \AA) [13]; this is typical of the bond strengthening/shortening due to M^+ or M^{2+} insertion. With regard to the interactions between the $[\text{N}_2\text{H}_3\text{BH}_3]^-$ anions, the average intermolecular $\text{H}^{\delta+}\cdots\text{H}^{\delta-}$ distance is about 2.16 \AA , which is longer than the distance in HB (2.01 \AA) and shorter than the sum of the van der Waals radii for two H atoms (2.4 \AA) [13]. These interactions, together with the van der Waals interactions between the cation and the anionic entities, take part to the stabilization of the solid state of $\text{Ca}(\text{HB})_2$ [34].

Figure 4. Crystal structure of $\text{Ca}(\text{HB})_2$ along the a , b and c crystallographic axes. The white, pink, blue and green spheres correspond to the H, B, N and Ca atoms respectively.

As mentioned in the introduction, Wu et al. [17] attempted a synthesis of $\text{Ca}(\text{HB})_2$ by ball-milling CaH_2 and HB (mol ratio 1:2) at 200 rpm for 3h. They reported a partial XRD pattern without further exploitation. We compared it to the pattern we collected here: some of the peaks are comparable to ours for a 2θ range likely between 5 and 15° , and the others look like belonging to unreacted HB. In other words, Wu et al. were able to recover a $\text{Ca}(\text{HB})_2$ -containing solid by using a planetary mill (Fritsch Pulverisette 7), whereas we failed to synthesize it by using a different planetary mill (Retsch PM 100) [21]. Interestingly, with respect to the polymorphic LiHB, Wu et al. [17] synthesized the high-temperature phase with their planetary mill, whereas we synthesized the low-temperature phase with ours. These two different achievements indicate first that the device used by Wu et al. is more energetic in comparable milling conditions, and second that synthesis of a HB derivative is also sensitive to the apparatus used.

Figure 5. Asymmetric unit showing the coordination around the cation Ca^{2+} , and inter- and intra-atomic distances obtained for $\text{Ca}(\text{HB})_2$ in **2**.

3.3. Molecular analysis of $\text{Ca}(\text{HB})_2$

2 was analyzed by ^{11}B MAS NMR spectroscopy (Figure 6). The spectrum shows a single split signal centered at -24 ppm, typical of a quadrupolar coupling for an NBH_3 environment. The electron repartition around the B element is anisotropic. This is different from the isotropy and the single Gaussian-like signal reported for the alkali derivatives, where the strong interaction

between M^+ ($M = \text{Li}, \text{Na}, \text{K}$) and BH_3 substantially smooths the electronic repartition around B [17,18,20,22]. With **2**, the larger atomic size and lower electropositivity of Ca^{2+} would make the $\text{Ca}^{2+}\cdots\text{H}^{\delta-}-\text{B}$ interactions weak enough not to modify the anisotropic repartition of electrons around B [9,10]. Our observation is in fact consistent with the signature reported for $\text{Ca}(\text{NH}_2\text{BH}_3)_2$ [35]. The spectrum of **2** shows a small deviation of the baseline between 0 and -15 ppm ascribed to N_2BH_2 and N_3BH environments that we usually see because of the high-speed rotation of the spectrometer rotor. However, we cannot discard dehydrocoupling in small extent of HB molecules when **1** was heated.

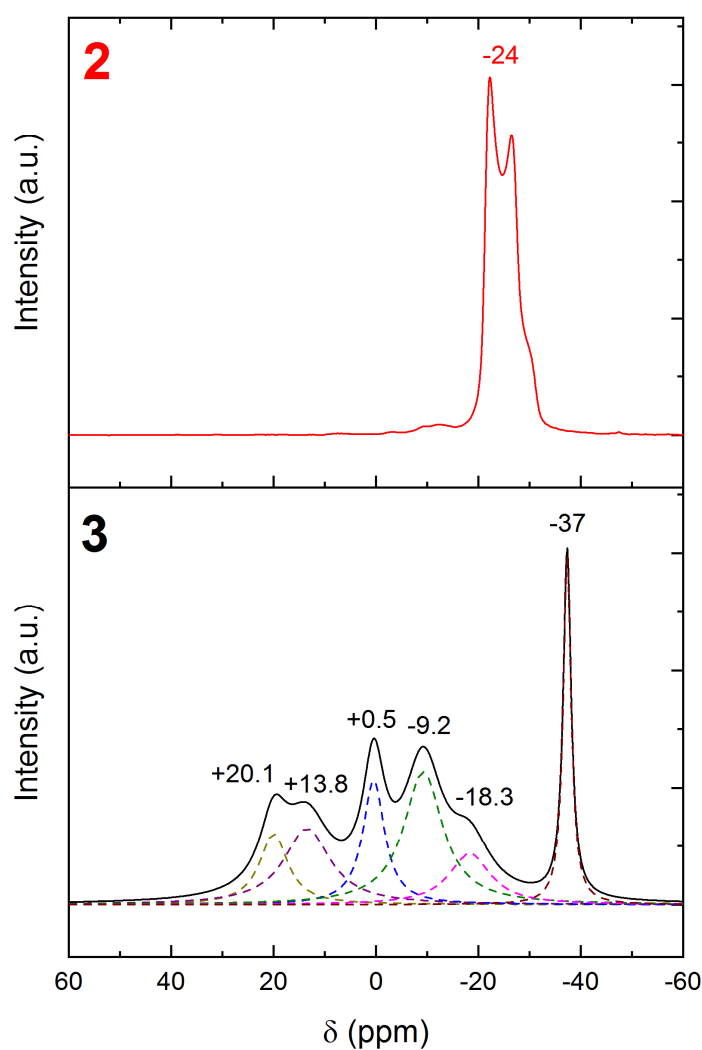

Figure 6. ^{11}B MAS NMR spectra of **2** and **3**. The chemical shifts (in ppm) of the signals are given. For **3**, the deconvoluted signals are shown in dashed lines.

2 was also analyzed by ^{43}Ca MAS NMR spectroscopy (Figure 7). The spectrum shows one broad and asymmetric signal which maximum is at 58.1 ppm. It cannot be ascribed to CaH_2 (+94.4 ppm) [36]. The chemical shift of the nucleus ^{43}Ca is sensitive to the (Pauling) electronegativity of the element with which Ca^{2+} interacts. As Ca^{2+} interacts with N ($\chi_{\text{N}} = 3.04$) of the anion $[\text{N}_2\text{H}_3\text{BH}_3]^-$, the signal belonging to **2** is expected to appear at lower chemical shift (+58.1 ppm) than the signal due to CaH_2 (+94.4 ppm; $\chi_{\text{H}} = 2.2$) and at higher chemical shift than that for e.g. CaF_2 (-1.4 ppm; $\chi_{\text{F}} = 3.98$) [37]. These observations support the formation of **2**. The presence of an additional signal of low intensity at +71.4 ppm, i.e. between the signal ascribed to **2** and that of CaH_2 , cannot be discarded. It may belong to an intermediate species such as $\text{HCa}(\text{N}_2\text{H}_3\text{BH}_3)$ (Eq. 2).

Figure 7. ^{43}Ca MAS NMR spectra of **2** and of CaH_2 . The chemical shifts of the prominent signals are given. The hatched area aims at distinguishing the possible signal at +58.1 ppm in the background noise.

2 was analyzed by FTIR spectroscopy (Figure 8). The spectrum is typical of a compound containing N–H, B–H, N–N and B–N bonds. The vibrational modes of N–H are represented by the bands at 3500–2500 cm^{-1} for symmetric and asymmetric stretching, and 1650–1300 cm^{-1} for asymmetric and symmetric wagging. The band at 1334 cm^{-1} has been assigned to N–N bending and that at 100–940 cm^{-1} for twisting and/or rocking. The vibrational modes of B–H can be seen

through the bands at 2500-2100 cm^{-1} for symmetric and asymmetric stretching, and at 1300–1100 cm^{-1} for wagging and/or rocking. The N–N bond is mainly characterized by the band present at 1000 cm^{-1} (stretching). The B–N bond can be seen *via* the symmetric stretching mode at 746 cm^{-1} . Compared to the spectrum of HB [13], the B–H stretching bands of **2** show red shifts, indicating weakened B–H bonds. The N–H stretching region is as complex, with bands showing blue (2950 cm^{-1}), red (3210 and 3033 cm^{-1}), or negligible (3330, 3268 and 2661 cm^{-1}) shifts. This is consistent with cation-induced changes in the electronic densities of the anion $[\text{N}_2\text{H}_3\text{BH}_3]^-$ [15,38].

Figure 8. FTIR spectra of **2** and **3**. The vibration bands have been assigned and the wavenumbers (cm^{-1}) are shown.

3.4. Thermal analysis and dehydrogenation properties of **2**

The gravimetric hydrogen density of pure $\text{Ca}(\text{HB})_2$ is 9.3 wt% H. The figure is high enough to consider the compound as a possible solid-state hydrogen carrier, provided it is able to release H_2 in mild conditions. Such a potential can be easily assessed by thermal analysis.

2 was analyzed by TG-MS and DSC over the temperature range 50-300°C at which CaH_2 is thermally stable (Figure 9). The curves can be divided into three distinct parts. (i) The part between 50 and about 90°C shows a weight gain of about 1.5 wt%. This is due to a “buoyancy” effect associated to the slow evolution of H_2 in an argon-filled semi-closed crucible (i.e. an

aluminum crucible sealed with a cap having a small hole); this happens when argon (heavier than H₂) is slowly expelled from the crucible while lighter H₂ forms. The H₂ release is slightly exothermic as evidenced by the very small hump on the DSC curve over the aforementioned temperature range. (ii) The second part of the curves starts from about 90°C and ends at about 170°C. **2** mainly dehydrogenates. The H₂ evolution followed by MS shows a maximum of intensity at 133°C. There is a concomitant release of N₂. This is in fact typical of MABs [17-22]. Volatile (unwanted) by-products like NH₃ and N₂H₄ are also generated. This indicates decomposition of **2** to some extent. The DSC curve shows a large exothermic wave, suggesting that the overall process is rather complex. (iii) The third part of the curves, starting from about 170 °C, is characterized by the evolution of H₂ only. At 300°C, the weight loss of **2** is 12 wt%, which is higher than the gravimetric hydrogen density of Ca(HB)₂ by 2.7 wt%, thus consistent with the release of N₂, NH₃ and N₂H₄ together with H₂.

It is interesting to compare the DSC curves of **2** and **1** (Figures 2 and 9). Between about 50 and 90°C, **1** shows melting (endothermic signal) and evolution (subsequent exothermic signal); **2** does not evolve (fairly stable over the temperature range). The fact remains that **1** transforms into **2**. Above 90°C, the DSC profiles of **1** and **2** are superimposable, confirming that **1** transformed into **2**.

2 does not melt. The DSC curve (Figure 9) does not show any endothermic process. We visually inspected the sample when heated up to 100°C and it did not show a change of physical state.

Dehydrogenation of B-N-H materials is generally compared at e.g. 200 °C. At such a temperature, the weight loss for **2** is 5.3 wt%. By ignoring the release of by-products, one may assume the evolution of roughly 3 equiv H₂ (out of a maximum of 6). The dehydrogenation extent of **2** is lower than that of amidoboranes [11,30,39-41] and hydrazinidoboranes [17,20,22] (Table 2). The destabilization effect of Ca²⁺ is less important than for Li⁺, Na⁺ and K⁺. This is confirmed by the FTIR spectrum of the thermolytic residue, denoted **3**, forming upon heating **2** up to 200°C (Figure 8): the B–H and N–H vibration bands are weakened and broadened in comparison to those of **2**, but they are still relatively high in comparison to those observed for polymeric residues formed by extensive dehydrogenation of e.g. AB, like cross-linked

polyiminoborane and polyborazylene [42]. Interestingly, comparable thermolytic properties were reported for $\text{Ca}(\text{NH}_2\text{BH}_3)_2$, which liberated about 3.4 equiv H_2 up to 200°C [30].

Figure 9. (top) Thermogravimetric analysis of **2**, compared to the results obtained for CaH_2 and pristine HB; the three parts mentioned in the manuscript are delimited by the vertical grey dashed lines; the symbol \blacklozenge in red placed on the TG curve of **2** indicates the weight loss at 200°C . (middle) Differential scanning calorimetry analysis of **2**, compared to that of **1**. (bottom) Mass spectrometry analysis of the gas liberated by **2** (with H_2 $m/z = 2$; NH_3 $m/z = 17$; N_2 $m/z = 28$; N_2H_4 $m/z = 32$).

Table 2. Comparison of amidoboranes (MAB = MNH_2BH_3 , and $\text{M}(\text{AB})_2 = \text{M}(\text{NH}_2\text{BH}_3)_2$) and hydrazinidoboranes (MHB = $\text{MN}_2\text{H}_3\text{BH}_3$, and $\text{M}(\text{HB})_2 = \text{M}(\text{N}_2\text{H}_3\text{BH}_3)_2$), based on their gravimetric H density (ρ_{H} in wt%), onset temperature of dehydrogenation (T_{onset} in °C) observed by thermogravimetric analysis, dehydrogenation extent at 200°C (n_{H_2} per mol of anion $[\text{NH}_2\text{BH}_3]^-$ or $\text{N}_2\text{H}_3\text{BH}_3^-$), and, in any, the list of the by-products found together with H_2 .

Family	Compound	ρ_{H} (wt%)	T_{onset} (°C)	$n_{\text{H}_2}/n_{\text{anion}}$	By-products	Ref.
MAB	LiAB	13.7	ca. 70	1.9	none	[39]
	NaAB	9.5	ca. 57	2	none or NH_3 ^a	[11,40]
	KAB	7.3	ca. 66	2	none	[41]
$\text{M}(\text{AB})_2$	$\text{Ca}(\text{AB})_2$	10.1	ca. 75	1.7 ^b		[30]
MHB	LiHB	11.7	ca. 70	2.4	N_2 , NH_3	[17]
	NaHB	8.9	ca. 60	2.6	N_2 , NH_3 , N_2H_4	[20]
	KHB	7.2	ca. 50	3	N_2 , NH_3	[22]
$\text{M}(\text{HB})_2$	$\text{Ca}(\text{HB})_2$	9.3	ca. 64	1.5 ^c	N_2 , NH_3 , N_2H_4	Present work

^a There is a contradiction about the purity of H_2 in ref. [11] vs. ref. [40].
^b i.e. 3.4 equiv H_2 for 1 equiv $\text{Ca}(\text{AB})_2$.
^c i.e. 3 equiv H_2 for 1 equiv $\text{Ca}(\text{HB})_2$.

The thermolytic residue **3** mentioned above is mostly amorphous (Figure S4). This is typical of any dehydrogenated B-N-H materials. Few diffractions peaks of very low intensity can however be seen. They are possibly attributed to CaH_2 . Given that CaH_2 in pristine state is stable up to 300°C (Figure 9), the significant decreases of the CaH_2 diffraction peaks from **2** to **3** suggests that, between 100 and 200°C, CaH_2 would have reacted with the $[\text{NH}_2\text{BH}_3]^-$ anions. The few diffraction peaks may also be interpreted as the occurrence of another minor phase like calcium borohydride $\text{Ca}(\text{BH}_4)_2$ [43]. **3** is of complex composition as evidenced by the presence of several boron resonances in the ^{11}B MAS NMR spectrum (Figure 6). One highly hydrogenated environment with BH_4 (−37 ppm) is attributed to in situ formed BH_4^- ; it may belong to $\text{Ca}(\text{BH}_4)_2$, which is known to be stable up to ca. 350 °C. Its formation could rationalize the low dehydrogenation extent discussed above. The spectrum also shows NBH_3 , N_2BH_2 , and/or N_2BH environments (−18.3 and −9.2 ppm). They are typical of oligomeric/polymeric molecules with the structural units $[-\text{NH}_2\text{BH}_2-]$ and $[-\text{NHBH}-]$, and for which the terminal group is NBH_3 [6]. At positive chemical shift, there is a first signal at +0.5 ppm. It is ascribed to a BN_4 environment [44]. Tri-coordinated boron elements with BN_3 (+13.8 ppm) and BN_2H (+20.1 ppm) environments are also distinguished. They are typical of polyborazylene-like compounds [45]. Such a complex composition is problematic for the development of an efficient regeneration path.

Little is known about the dehydrogenation and/or decomposition paths of MHB leading to the aforementioned polymeric residues. The overall path of dehydrocoupling is complex. For example, it has been demonstrated that heteropolar $\text{H}^{\delta+}\dots\text{H}^{\delta-}$ and homopolar $\text{H}^{\delta-}\dots\text{H}^{\delta-}/\text{H}^{\delta+}\dots\text{H}^{\delta+}$

reactions competitively occur [46,47] resulting in NBH_3 , N_2BH_2 , N_2BH , BN_3 , BN_2H , and BN_4 environments. Otherwise, we may try to clarify the likely presence of $Ca(BH_4)_2$ as by-product. We hypothesize the formation of $[Ca(N_2H_3)_2BH_2]^+[BH_4]^-$ as intermediate by Ca^{2+} -mediated hydride transfer from BH_3 of one $[N_2H_3BH_3]^-$ anion to BH_3 of the other anion, the transfer being accompanied by a scission of the N–B bond of the latter anion:

The formation of such transient Ca–H is based on the metal ion assisted hydride transfer mechanism reported for e.g. LiHB [35,48] and $Ca(NH_2BH_3)_2$ [49]. Dehydrocoupling is suggested to take place via a major path and a minor path (where the participation of the remaining CaH_2 is ignored). For the major path, all of the hydrogens would be likely to participate to H_2 evolution, such as:

With respect to the minor path, only the $(N_2H_3)_2BH_2$ ligands would be involved:

The entities N_2H_3 , that are twice more concentrated than the BH_2 groups, could then explain the evolution of N_2H_4 , NH_3 and N_2 as volatile by-products:

To support these mechanisms, further works, implemented by theoretical calculations, are required. Beforehand, it would be preferable to succeed in synthesizing a pure phase of $Ca(HB)_2$.

Hügler et al. [12] demonstrated that the binary mixture LiH-HB is preferable to pristine HB owing to faster dehydrogenation kinetics. It is even more attractive than LiHB on the basis of the gravimetric hydrogen density (15 and 11.7 wt% H respectively). A similar comparison can be made for **1**, our binary mixture CaH_2 -2HB, and pure $Ca(HB)_2$. (i) They respectively have a gravimetric hydrogen density of 12.05 and 9.3 wt% H. (ii) **1** is able to release H_2 from about 40°C [21]: 2 equiv H_2 are formed by reaction of the two $H^{\delta-}$ of CaH_2 with one $H^{\delta+}$ of each HB molecule. Assuming that both **1** and $Ca(HB)_2$ liberate 3 equiv H_2 from about 100 to 200°C, the H_2 release capacity of **1** is then higher, with 5 equiv H_2 (i.e. 7.5 wt% H released). (iii) The weight loss at 200°C determined by TG analysis is 15.5 wt% for **1**, which supposes an important amount of N_2H_4 probably due to

some unreacted HB. Superior H₂ purity could be expected provided that improvements in the sample preparation (further optimization of the milling, mixing using an anhydrous solvent, etc.) are made. What is clear from this short comparative analysis is that any further work should focus on a pure phase of Ca(HB)₂ as well as on the binary mixture CaH₂-2HB.

4. Conclusion

In situ synchrotron thermodiffraction experiments, coupled with DSC analyses, allowed us to synthesize the hitherto elusive calcium hydrazinidoborane Ca(N₂H₃BH₃)₂. From a binary mixture of calcium hydride CaH₂ and two equivalents of hydrazine borane N₂H₄BH₃, calcium hydrazinidoborane (monoclinic, s.g. *Ic*) forms above 45°C, especially at around 60°C, the temperature at which HB has melted and is liquid. The as-obtained sample is actually a mixture of Ca(N₂H₃BH₃)₂ as the main phase and some unreacted CaH₂. Beyond 70°C, the diffraction peaks of Ca(N₂H₃BH₃)₂ decay and they cannot be seen above 97°C anymore. This suggests the decomposition of the new phase, which was confirmed by thermal analyses. The calcium hydrazinidoborane-rich solid dehydrogenates within the temperature range 90-170°C, and some decomposition into volatile by-products (N₂, NH₃ and N₂H₄) also takes place. In any event, Ca(N₂H₃BH₃)₂ shows better dehydrogenation properties than the parent N₂H₄BH₃. The thermolytic residue obtained at 200°C is typical of any dehydrogenated B-N-H materials: it is amorphous and of complex composition. As it stands, Ca(N₂H₃BH₃)₂ may be regarded as having a potential for hydrogen storage but additional works, notably targeting a pure phase, are required. This is all the more important as further efforts might open other opportunities (e.g. boron nitride ceramics).
