Abstract

Little is known about differences between induced pluripotent stem cells produced from tissues originating from the same germ layer. We have generated human myoblast-derived iPS cells by retroviral transduction of human primary myoblasts with the OCT3/4, SOX2, KLF4 and MYC coding sequences and compared them to iPS produced from human primary fibroblasts. When cultivated in vitro, these iPS cells proved similar to human embryonic stem cells in terms of morphology, expression of embryonic stemness markers and gene promoter methylation patterns. Embryonic bodies were derived that expressed endodermal, mesodermal as well as ectodermal markers. A comparative analysis of transcription patterns revealed significant differences in the gene expression pattern between myoblast- and fibroblast-derived iPS cells. However, these differences were reduced in the mesenchymal stem cells derived from the two iPS cell types were compared.

Introduction

The induced pluripotent stem (iPS) cells approach has opened unprecedented possibilities for the generation of patient-specific pluripotent stem cells useful for studies on the origin of various pathologies as well as for possible corrections of genetic defects and cell transplantation therapies [1] [2,3]. iPS cells now represent a potentially inexhaustible cell resource with a differentiation potential similar to that of embryonic stem (ES) cells. Somatic cells can be reprogrammed to a pluripotent state by transduction of either OCT4, SOX2, NANOG, and LIN28 [4] or OCT4, SOX2, KLF4 and MYC [5,6] coding sequences, or alternatively by RNA or protein transduction approaches [7]. iPS cells resemble ES cells in terms of epigenetic and gene expression patterns, morphology, and ability to differentiate into endodermal, mesodermal and ectodermal derivatives [4,5,6,8].

Up till now, human iPS cells have been generated mostly from parental fibroblasts of diverse origin [6,9,10], keratinocytes [8] and mesenchymal stromal cells [11]. In humans, iPS cells have recently been obtained from both differentiated human muscle and from skeletal muscle stem cells [12,13]. We have independently produced induced pluripotent stem cells from human primary myoblasts which specifically expressed CD56 at their cell surface and were isolated from muscle biopsies prior to being maintained in cell culture. In conditions of serum starvation, these primary myoblasts differentiated into myotubes under the control of a core transcriptional network determined by myogenic regulatory factors including MYF5, MYOD, myogenin and MRF4 [14,15].

Earlier studies had indicated that iPS cells retained the transcription memory of the germ layer origin of their parental somatic cells [16,17] [18]. It was not clear, however, whether iPS cells generated from parental cells sharing the same germ layer origin would display a common expression pattern. In the present paper, we compare gene expression in differentiating iPS cells produced from either myoblasts or fibroblasts.

Materials and Methods

All cell lines used in this study are presented in Table S1.

Myoblast isolation and culture

Human primary myoblasts were isolated from skeletal muscles (quadriceps) as described in [14], purified with immuno-magnetic sorting system (Miltenyi Biotec, USA) using an anti-CD56/NCAM antibody (BD Biosciences) according to the manufactur-
er’s specifications. CD56-positive myoblasts were seeded in collagen-coated Petri dishes (P1) and cultured in DMEM, supplemented with 10% foetal calf serum, 1% UltraRPMI (Biosepra), at 37°C with 5% CO₂. Myoblast purity was determined by staining for desmin (Sigma). The cells were used at passage 1 to passage 3 for the generation of iPS cells.

**Fibroblast isolation and culture**

Human normal adult fibroblasts (Coriell cell repository) were maintained in DMEM high glucose supplemented with 10% foetal calf serum, 1 mM sodium pyruvate (Invitrogen) and 2 mM glutamax (Invitrogen).

**iPS cell culture**

iPS cell lines from primary human fibroblasts were previously obtained and characterized at the Institute for Stem cell Therapy and Exploration of Monogenic Diseases, (I-Stem, Evry France) [19].

iPS cell lines from primary human myoblasts were generated in this work in collaboration with I-Stem (Evry France) by infection with retroviral cassettes harbouring the cDNA encoding OCT4, SOX2, c-MYC and KLF4, and GFP under transcriptional control of its promoters (Addgene,Cambridge, MA) (Addgene plasmids 17220, 17225, 17226, 17227). These plasmids were individually transfected using FuGene (Roche) into PLAT-A (for amphotropic viral production) packaging cells. PLAT-A cells medium was replaced 24 hours post-transfection. Viral supernatants were collected 48 hours post-transfection, filtered through a 0.45 μm filter, then mixed at a 1:1:1 ratio.

iPS cells were cultured either on mouse embryonic fibroblasts (MEF) prepared from E14 mouse embryos or on human foreskin fibroblasts (BJ1) feeder cells which were mytomycin-C growth-arrested, BJ1 cells express GFP and FGF2 protein were prepared at the iSTEM platform. hES culture medium was KO/DMEM (Invitrogen) supplemented with 20% FCS, 0.1 mM nonessential amino acids (NEAA) (Invitrogen), 2 mM glutamate, 50 μM β-mercaptoethanol (Invitrogen), 100 UI/ml penicillin/streptomycin (Invitrogen). hES cell medium for MEF feeder was supplemented by 10 ng/ml fibroblast growth factor FGF2 (Invitrogen). The iPS cells were passaged every 7 days.

**Retroviral Transduction**

Cryovial of Platinum-A (PlatA) cells (Cell Biolabs) were used for transient virus packaging. 3×10⁶ PlatA cells were plated per 60 mm gelatine-coated dish (80% confluent) in PlatA medium of DMEM+Glutamax II (Invitrogen) containing 10% foetal calf serum, 1 mM sodium pyruvate (Invitrogen) and 50 mM β-mercaptoethanol. After 24 h incubation pMYG retroviral vectors containing hOCT4, hSOX2, hKLF4, hMYC and GFP were transfected into PlatA cells with FuGENE HD transfection reagent (Roche). After 48 h viral supernatants were collected, filtered in the tubes with polybrene/HEPES mixture. Adult somatic cells were infected with a mixture of viral supernatant containing each reprogramming factor in equal quantity. The transduction efficiency was checked by expression of GFP FACS analysis (MACSQuant of Miltenyi).

**Generation of iPS Cells from Myoblasts**

Four days before the transduction, 2.5×10⁴ cells or 50×10⁴ cells were seeded onto 25 mm plates. One day before retroviral infection, the myoblast cells were seeded at 10⁴ cells per well in 6-well plates. The viral supernatant was added only one as it was sufficient. One day after transduction the cells were seeded in 6-well collagen-coated plates at different dilutions: 5×, 10×, 30×, 40× and 80×, in the myoblast medium. After 24 h the myoblast medium was replaced with hES cell medium supplemented with 10 ng/ml FGF2 and 0.5 mM valproic acid (VPA) (Sigma-Aldrich) for 10 days. The medium was replaced every day and VPA has been omitted from culture medium from day 11. Around 3–5 weeks after viral reprogramming, iPS colonies were picked every day on the basis of ES cell-like morphology. The iPS colonies were transferred onto BJ1-FGF2 feeder plates and maintained in hES cell medium. ROCK inhibitor (Calbiochem) was added at 10 μM during the first three days to enhance survival of dissociated iPS cells.

**MSC Differentiation**

The iPS cells were directly differentiated into MSC cells by serum induction. The iPS cells were incubated in MSC medium containing KO/DMEM (Invitrogen) supplemented with 20% FCS, 0.1 mM nonessential amino acids (NEAA) (Invitrogen), 2 mM glutamate, 50 μM β-mercaptoethanol, 100 UI/ml penicillin/streptomycin (Invitrogen). The medium was changed every 2–3 days. FGF2 (10 ng/ml) and Vitamin C (1 mM; Sigma) were added up to the first passage. After passages P4–P5, cells were seeded at 4000 cells/cm².

**Embryoid Body Formation**

Human iPS cells were treated with collagenase (Invitrogen), harvested and transferred to low attachment culture 6-well plates (NalgeNunc) in hES cell medium without FGF2. These cell aggregates were allowed to grow for several days or weeks and samples were harvested at various time points for differentiation markers analysis.

**RNA Isolation and Reverse Transcription**

Total RNA was extracted using the Qiagen RNA-easy Kit from iPS cells at passages 22–25, from MSC at passages 6 and from primary myoblasts at passage 6. cDNA was synthesized from 500 ng of total RNA using RevertAid H Minus First Strand cDNA Synthesis Kit (Fermentas) for RT-PCR analysis. PCR primer sequences are shown in Table S2. Total RNA was isolated for transcriptome analysis using Trizol (Invitrogen), according to the manufacturer’s instructions.

**Bisulfite Pyrosequencing Analysis**

Genomic DNA was isolated using the Wizard SV Genomic DNA purification system (Promega). Quantitative DNA methylatation analysis was performed by pyrosequencing of bisulfite-treated DNA [20]. 500 ng of DNA was bisulfite converted using the EpiTect 96 Bisulfite kit (Qiagen, Hilden, Germany) according to the manufacturer’s instructions. Two regions in OCT4 and one in N-ANOG were amplified using 30 ng of bisulfite-treated human genomic DNA and 5 to 7.5 pmol of forward and reverse primers, one of them being biotinylated. Oligonucleotide sequences for PCR amplification and pyrosequencing are given in Table S3. Reaction conditions were 1x HotStar Taq buffer supplemented with 1.6 mM MgCl₂, 100 μM dNTPs and 2.0 U HotStar Taq polymerase (Qiagen) in a 25 μl volume. The PCR program consisted of a denaturing step of 15 min at 95°C followed by 50 cycles each of 30 s at 95°C, 30 s at the respective annealing temperature and 20 s at 72°C, with a final extension step of 3 min at 72°C. 10 μl of PCR product were rendered single-stranded as previously described [20] and 4 pmol of the respective sequencing primers were used for analysis. Quantitative DNA methylation
Alkaline Phosphatase Staining and Immunocytochemistry

iPS cells were washed with PBS, fixed in 4% paraformaldehyde in PBS for 15 minutes, then rinsed with PBS. To allow nuclear permeation, the cells were treated with 50 mM NH₄Cl (Sigma) for 10 minutes, rinsed with PBS and treated with 0.2% Triton X-100 (Sigma) in PBS for 4 minutes. After PBS washes, cells were blocked in 0.5% bovine serum albumin (Sigma) in PBS for 30 minutes. Cells were stained with the following primary antibodies: hOCT3/4 (1:200; goat; Santa Cruz Biotechnology); SSEA-4 (1:100; goat; BD Biosciences), TRA-1-60 (1:100; mouse; Millipore), TRA-1-81 (1:100; mouse; Millipore). Appropriate Alexa Fluor 488-conjugated secondary antibodies (Invitrogen) were used at a 1:1,000 dilution. DAPI was added at 0.1 ng/ml. Alkaline phosphatase staining was performed according to manufacturer’s instructions (Sigma Aldrich).

Flow cytometry analysis

The following PE-conjugated human monoclonal antibodies were used for the flow cytometry analysis at 1:5 dilutions: the iso-IgG1 (BD Biosciences), anti-CD29 (BD Biosciences), anti-CD44 (BD Biosciences), anti-CD73 (BD Biosciences), anti-CD105 (Abcys), and anti-CD166 (BD Biosciences). The samples were analyzed on MACSQuant (Miltenyi).

Karyotype Analysis

Karyotyping analysis was performed on every iPS cell line at passage 22. Actively growing iPS cell colonies were treated with colchicine at 20 μg/ml (Eurobio) for 90 minutes at 37°C. After washing, cells were incubated in trypsin-EDTA 0.05% (Eurobio) for 2–3 minutes and harvested. Cells were incubated in 75 mM KCl (Sigma) for 10–14 minutes at 37°C, followed by fixation with 3:1 methyl alcohol/glacial acetic acid. Fixed cells were dropped on wet slides and dried at 37°C for 24 hours. Chromosomal G-band analysis and multicolour FISH were performed at Kremlin Bicetre Hospital.

Microarray Expression Analysis

The quantity and purity of the extracted RNA was evaluated using a NanoDrop spectrophotometer. Its integrity measured using an Agilent Bioanalyzer. For microarray hybridizations, 500 ng of total RNA from each RNA sample was amplified and labelled with fluorescent dye (Cy3) using the Low RNA Input Linear Amplification Labelling kit (Agilent Technologies, Palo Alto, CA, USA) following the manufacturer’s protocol. Cy3-labeled cRNA were hybridized to the Agilent Human 44K Whole Genome Oligo Microarray (Agilent Technologies), prior to washing and scanning. Data were extracted from scanned images using Feature Extraction software (v 10.5.1.1 Agilent) with default settings.

Gene Expression Analysis

Gene expression analysis was carried out using R and Bioconductor [Gentleman 2004]. After removal of probes with an intensity lower than background in more than two samples, the dataset was reduced from ~41,000 to ~38,600 probes. Normalization was performed using vsn library [21]; for each array, a scaling factor is found that makes the as similar as possible data across arrays, using least squares regression. The generalised log-transformation is applied to the spot intensities. Differential expression analysis of normalized data was performed using limma package [22], allowing simultaneous comparisons between more than two mRNA targets by fitting a linear model to the expression data for each probe. The genes differentially expressed between fibroblasts and myoblasts, iPS derived from myoblasts (miPS) and MSC derived from miPS respectively (resulting in three contrasts) have been identified using an Empirical Bayesian approach, robust for small numbers of arrays and equivalent to shrinkage of the estimated sample variances towards a pooled estimate, resulting in a stable inference when the number of arrays is small [Smyth 2004]. For each target probe, a moderated t-statistic variable was computed, accompanied by an adjusted P-value obtained with the Benjamini-Hochberg procedure for multiple test adjustment. Sets of genes with adjusted P-value<0.05 and log(Odds(Probe differentially expressed))>0 were selected as differentially expressed.

We have included two fiPS samples grown on MEF feeder for analysis of gene expression of a list of muscle-specific genes in fiPS and miPS (Tables 1 and 2). These two samples had a slightly different expression pattern as compared to fiPS grown on human BJ1 feeder. If the absolute log(fold-change) between the expression values of MEF_fiPS and BJ_fiPS stemming from the same cell line was smaller than 1.5, an additional comparison is made between the expression of the three fiPS and four miPS samples, a classical t-test was performed and the corresponding p-value was reported (in Table 2).

Functional Analysis

Functional analysis for the differentially expressed genes in the various contrasts was carried out using annotate and GOstats packages from Bioconductor. The hypergeometric P-values for overrepresentation of genes for all GO terms in the induced GO graph were computed. This is based on the idea of comparing the frequency of genes annotated with a particular GO term among the differentially expressed genes with the overall frequency of this particular GO term among all genes represented on the array. Biological Process (BP) GO terms with a P-value<0.1 have been selected. GO terms related to muscular function were selected from the significant BP GO terms.

The gene ontology (GO) terms as well as other system descriptors were also analysed by Set distiller feature of GeneDecks Version 3 analysis tool (http://www.geneCards.org), ranked by significance of enrichment, which was denoted by P-value>0.05 and corrected for multiple testing by Bonferroni correction.

Results

Generation of iPS cells from purified primary myoblasts

Primary CD56+ myoblasts purified from a quadriceps biopsy were infected using retroviral vectors containing human OCT4, SOX2, C-MYC and KLF4 coding sequences and GFP (see Materials and methods). One day after transduction verified by GFP expression, virally-infected cells were seeded into 6-well collagen-coated plates at various dilutions and grown in human ES cell culture medium. The first colonies with a human ES-like morphology were harvested three weeks after reprogramming (Figure 1). These colonies were then grown on BJ1 fibroblasts used as an FGF2-producing feeder. In such conditions, iPS cells are maintained in a pluripotent state. They are referred to as myoblast-derived induced pluripotent stem (miPS) cells.

Characterization of miPS cells

To characterize the clones obtained, ES cell markers were first searched on 10 to 20 colonies immunocytochemically stained. As exemplified for two miPS cell-lines, (Figure 2A) all colonies proved positive for the ES cell-specific surface antigens SSEA-4, TRA-1–60 and TRA-1–81 as well as for the ES cell-specific transcription factor OCT3/4, consistent with an iPS cell phenotype. We then investigated the DNA methylation status in the promoter regions of the OCT3/4 and NANOG genes. In the three miPS cell-lines tested, both promoters were found to be less methylated than in parental somatic cells (Figure 2B), indicating that both genes had been activated. The miPS1 and miPS2 cell-lines were further analyzed for their karyotypes at passage 22 when both were found to be diploid and normal (Figure S1).

Expression of transgenes and endogenous stemness genes

Next, we examined transcription levels for various stemness marker genes. miPS cells were found to express undifferentiated ES cell marker genes including the reprogramming KLF4, OCT3/4, SOX2, MYC and NANOG genes, the developmental pluripotency-associated proteins DPPA2 and DPPA4 as well as GDF3 (Figure 2C, lanes 6–11). This expression was endogenous, all transduced genes being silent with the single exception of the transduced MYC gene which participated in total MYC expression until the MSC stage when it was found to be totally extinct (Figure S2). Untransduced parental cells only expressed MYC and KLF4 (Figure 2C, lanes 1–5) which were also expressed by the six MSC tested (Figure 2C, lanes 12–17).

Spontaneous differentiation of miPS cells

In order to examine the potential of miPS cells to differentiate into each of the three germ layers, we used a floating culture approach whereby miPS cells were found to generate spherical embryoid bodies (EB) of spontaneously differentiating cells. As displayed in Figure 3A, aggregates were observed as early as day 4, followed by fusion of two or more EBs which formed larger

Spontaneous differentiation of miPS cells

In order to examine the potential of miPS cells to differentiate into each of the three germ layers, we used a floating culture approach whereby miPS cells were found to generate spherical embryoid bodies (EB) of spontaneously differentiating cells. As displayed in Figure 3A, aggregates were observed as early as day 4, followed by fusion of two or more EBs which formed larger

Red staining from PE-conjugated human monoclonal antibodies, green from GFP-expressing BJ1 feeder, and blue for DAPI. Scale bars = 100 μm. B, DNA methylation status of CpG dinucleotides in the OCT3/4 and NANOG gene promoter regions in parental (P) and miPS cells. C, Expression levels of pluripotency marker and reprogramming genes in parental (P) cells, iPS cells and iPS-derived MSC of fibroblast (f) and myoblast (m) lineages. Data were extracted from the 44K+ Agilent transcriptome array and scaled. Y axis, expression levels normalized against β-actin gene expression. The experiments were carried out in duplicate.
doi:10.1371/journal.pone.0053033.g002
aggregates of differentiated cells as shown at days 7 and 14 in Figure 3A. The self-aggregation process was associated with the appearance of different cell types. Markers associated with the three germ layers were expressed progressively at days 4, 7 and 14 in the two EB cell-lines mEB1 and mEB2 (Figure 3B). The mesodermal marker gene TNNT2 was strongly expressed in both lines as early as day 4 while the endodermal marker gene AFP and the ectodermal marker genes MAP2 and PAX6, detected at day 7, were more strongly expressed at day 14 (Figure 3B).

Further analysis was performed on the mEB1 cell-line. Expression levels of pluripotency, mesodermal, ectodermal and endodermal marker genes are displayed in Figure 4, panels A, B, C and D, respectively. For comparison purposes, the same analysis was performed on EB1 (EB1.D4 and EB1.D14) as well as on the corresponding parental (P1) and miPS (IPS1) cells and on derived MSC (MSC1). At day 4, EB1 cells were found to express the six stem markers tested as strongly as iPS cells. This expression decreased at day 14 (EB1.D14). Parental cells or MSC were negative (Figure 4A). All markers associated with the three germ layers were expressed at days 4 and/or 14 in the EB cell-line (Figure 4B–D). In general, mesodermal markers were expressed from iPS to EB and MSC stages of differentiation (Figure 4B) to a higher degree than the ectodermal and endodermal markers (Figure 4C–D). Together, these expression profiles indicated that the miPS cell lines were pluripotent since they could give rise to differentiated cells expressing markers of each of the three germ layers.

Targeted differentiation of miPS cells towards mesenchymal stem cells

We next submitted miPS cells to in vitro directed differentiation by incubation in culture medium supplemented with FCS, FGF2 and Vitamin C as described in Materials and Methods. The initially round shaped cells (Figure S3A, passage 0, day 2) progressively acquired a more elongated phenotype consistent with an MSC...
morphology. This was evident by day 21 when the cell culture was first passaged (P1). Two days later at passage 2, a population of long and thin MSC designated as mMSC (miPS-derived MSC; Figure S3B) was apparent in both mMSC1 and mMSC2. At passage 5, the two cell lines analyzed by flow cytometry similarly expressed MSC markers CD29 (integrin β-1), CD44 (chondroitin sulfate proteoglycan 8), CD73 (ecto-5’-nucleotidase), CD105 (endoglin) and CD166 (activated leucocyte cell adhesion molecule) at their cell surface (Figure 5).

Global gene expression analysis of genes differentially expressed in miPS cells, mMSC and myoblasts vs fibroblasts
Several studies have been dedicated to a comparative characterization of iPS cells produced from cells derived from the ectodermal, mesodermal or endodermal germ layers [16][18]. Here, we have compared gene expression profiles determined by Agilent cDNA microarrays in miPS cells that we produced from myoblasts with the iPS from fibroblasts that were previously produced and characterized at I-Stem (Evry, France) [19], both of mesodermal origin. In a search for a myoblast-specific signature, a functional analysis was performed along with an empirical Bayesian statistical approach to compare expression patterns in myoblasts, miPS cells and mMSC versus cells not belonging to the myogenic lineage. In the Venn Diagram exhibited in Figure 6, each circle represents a contrast between two expression profiles, revealing genes that have a common pattern of upregulation. Pairwise comparisons were carried out between miPS and fibroblasts (miPS_vs_fibro), mMSC and fibroblasts (mMSC_vs_fibro) and myoblasts and fibroblasts (myo_vs_fibro). Among the

Figure 5. Characterization of mMSC1 and mMSC2 surface antigens. The presence of CD29, CD44, CD73, CD105 and CD166 was detected by FACS analysis performed at passage 5.
doi:10.1371/journal.pone.0053033.g005
17,994 genes analyzed, 2,582 (14.3%) were more expressed in myoblasts than in fibroblasts (Figure 6, lower circle). Among them, 1,126 (1,066+60) were expressed to a higher level in miPS cells than in fibroblasts (Figure 6, intersection of the lower and upper left circles). However, those represented a small fraction only of the 5,806 genes (32.3%) that were more expressed in miPS cells than in fibroblasts (upper left circle). When mMSCs were compared with fibroblasts (Figure 6, upper right circle), the overall number of genes differentially expressed was only 410 (2.3% of total genes). All together, there were only 60 genes (0.3% of all genes analyzed, intersection of the three circles) that were expressed to a higher level in myoblasts, miPS cells and mMSC as compared to fibroblasts.

In order to see the fold change differences in gene expression profiles between the myoblast and fibroblast lineages, contrast profiles were determined looking at the top 100 most differentially expressed genes in mMSC vs fMSC, miPS vs fiPS cells and myoblast vs fibroblast parental cells. While the value of the log(Odds) was maximal by myoblastic and fibroblastic parental cells, differences between the two lineages were less important at the MSC stage (Figure S5). Strikingly, they were even less pronounced when miPS and fiPS cells were compared (Figure S5), confirming the observed similarity between mMSC and fMSC in terms of gene expression.

Functional analysis of genes more highly expressed in cells belonging to the myogenic lineage

We then turned to Gene Ontology descriptors to approach the function of the genes which were more highly expressed in the myogenic lineage than in fibroblasts. To this end, we searched our gene sets for shared system descriptors (see Materials and Methods). ACTA1 (alpha skeletal muscle actin), MIF2 (myosin, heavy chain 2, skeletal muscle, adult), TNNI3 (troponin T, slow skeletal muscle), ACTN2 (alpha-actinin skeletal muscle), TRIM63 (muscle-specific ring finger protein) and RIR1 (Skeletal muscle calcium release channel) were present among the 1,126 genes that were overexpressed in both miPS and myoblasts versus fibroblasts, exhibiting a high score of muscle phenotype and muscle GO-terms such as muscle contraction, muscle filament sliding, structural constituents of muscle, myogenesis and myopathy (see list in Table 1). The 94 genes that were more expressed in both mMSC and myoblasts versus fibroblasts are found in Table 2. The four genes with muscle-specific GO-terms were MYOZ2 (myozin), CA3 (carboxylic anhydrase III, muscle specific), PDLIM3 (actinin-associated LIM protein) and ANKRD1 (ankyrin repeat domain 1, cardiac muscle), a set different from that identified above in the miPS cell comparison.

Thus, a limited number of muscle-specific genes have been identified as following a pattern of upregulation in myoblasts and miPS cells versus fibroblasts (3.6% of all overexpressed genes) while an even smaller number of genes exhibited the same differential pattern extended to the miPS versus fiPS contrast. Finally, no muscle-specific genes were found to be significantly upregulated in mMSC as compared to fMSC (data not shown).

Differential expression analysis of muscle specific genes in the myoblast and fibroblast lineages across iPSC, MSC and differentiated cells

Finally, a closer look was given at the six genes, MEO1Z1, MEF2C, CKM, M11H6, TRIM63 and IGF2, classically associated with myogenesis (Figure 7, Figure S4) [23]. As expected, all six were more highly expressed in miPS than in fiPS cells (Figure 7 and Table S4). Strikingly, these differences were largely lost between MSC derived from miPS or fiPS cells (Figure 7, panel C and Table S4). IGF2 remained better expressed in mMSC than in fMSC, but the other five genes were expressed more highly in mMSC [MEO1Z1 and TRIM63] or similarly in both MSC types [CKM and M11H6]. These observations were reproducible within each category of cell lines (Table S4). Surprisingly, miPS and fiPS cells exhibited no differences in their expression levels of MyoD, myogenin, MRF4 and MEF2, the four core myogenic regulatory genes which together initiate the myogenesis process [15].

Discussion

In this work, we have produced iPSC cells from human MyoD-expressing CD36+ fully committed myogenic cells by retroviral transduction with OCT3/4, SOX2, MYC and KLF4 coding sequences. These miPS cells obtained expressed genes expected for iPSC cells, including OCT3/4 and NANOG which were activated as indicated by the decreased methylation of their promoters in comparison with their parental cell-lines. In addition, they were endowed with the capacity to differentiate into embryoid bodies which contained cells expressing surface makers characteristic of the three germ layers. That these miPS cells were pluripotent and functional was further demonstrated by their capacity to produce MSC which exhibited the CD29, CD44, CD73, CD105 and CD166 surface antigens but had lost expression of all stem cell markers. From earlier studies, iPSC cells are believed to retain the transcription memory of the germ layer origin of their parental somatic cells [16][18]. It is not clear, however, whether iPSC cells generated from parental cells sharing the same germ layer origin should display a common expression pattern. Here, we have carefully characterized gene expression in iPSC cells produced from either myoblasts or fibroblasts, both derived from the mesoderm. As anticipated, miPS and fiPS gene expression patterns were
found to reside within the same large cluster generated using an unsupervised HCA. Expression differences were less important between the four miPS cell lines than with the fiPS cell line which lay in a distinct subcluster. Interestingly, EB cells derived from one miPS cell-line and tested at either day 4 or day 14 localized to the same large cluster. The second large cluster generated from this HCA contained both myoblastic and fibroblastic parental cells which, however, mapped to distinct subclusters. Similarly, regardless of their miPS or fiPS cell derivation, all MSC lay within the same large cluster though in distinct subclusters. From this analysis of mesodermal derivatives, we conclude that the nature of the cells analyzed is less important than their stage of differentiation, e.g. miPS and fiPS cells on one hand, or mMSC

Figure 7. Expression of myogenic markers. and iMSC on the other hand, have more in common than with their parental myoblasts or fibroblasts, respectively.

The expression of several muscle-specific marker genes (actins, myosins, creatine kinase and others) was significantly stronger in miPS than in fiPS cells. Figure 7, Figure S5. In contrast, there were no significant differences between myoblast- and fibroblast-derived MSC. From the transcriptome analysis, however, four muscle-specific genes were found upregulated in muscle-derived mesenchymal stem cells and in myoblasts: ANKRDI (ankyrin repeat domain 1 (cardiac muscle)), TGFB2 (transforming growth factor, beta 2), PDGFA (Platelet-derived growth factor A chain) and PDLIM3 (Alpha-actinin-2-associated LIM protein). Two of them, ANKRDI and TGFB2, are highly expressed in mMSCs as in iMSCs. The PDGFA and PDLIM3 are highly expressed only in muscle lineage derivatives, miPS, mMSC and myoblasts. The PDGFA protein, the main determinant of alpha-actin filament polymerization, upregulates smooth muscle alpha-actin expression [24]. This factor mitogenic for cells of mesenchymal origin is also known as a paraxial mesodermal marker and has recently been proposed as a tool to sort mesenchymal cells with a substantial muscle regeneration potential [25,26]. PDLIM3 is a muscle specific protein involved in cytoskeletal assembly (actin filament organization) in skeletal muscles [27].

In conclusion, we have successfully generated and characterized iPS cells from human primary myoblasts and we have produced MSC from these miPS.
