HAL is a multi-disciplinary open access archive for the deposit and dissemination of scientific research documents, whether they are published or not. The documents may come from teaching and research institutions in France or abroad, or from public or private research centers.

L’archive ouverte pluridisciplinaire HAL, est destinée au dépôt et à la diffusion de documents scientifiques de niveau recherche, publiés ou non, émanant des établissements d’enseignement et de recherche français ou étrangers, des laboratoires publics ou privés.
Noninvasive ventilation (NIV) is increasingly used as a life-support therapy to prevent intubation during acute respiratory failure (ARF).

However, NIV failure is strongly associated with poor outcome. NIV usually refers to the use of pressure support ventilation (PSV) that seeks to synchronize ventilator insufflation in accordance with the patient’s effort.

Patient-ventilator synchronization is critical for reducing the work of breathing and for successful NIV. Although PSV allows the patient to influence the breathing pattern, ventilator cycling criteria may worsen the patient-ventilator interaction, and severe asynchronies occur in up to 43% of patients undergoing NIV for ARF.
Neurally adjusted ventilatory assist (NAVA) is an assisted ventilatory mode that delivers a pressure proportional to the integral of the electrical activity of the diaphragm (EAdi). Ventilator support begins when the neural drive to the diaphragm begins to increase, and pressure is cycled off when the respiratory centers end the EAdi. Compared with PSV, NAVA can reduce patient-ventilator asynchrony during invasive mechanical ventilation. To date, however, few data are available in patients receiving NIV for ARF. The aim of the present physiologic, prospective, crossover study was to compare the short-term effects of NAVA and PSV in delivering NIV with a facemask on patient-ventilator synchronization. We hypothesized that, compared with PSV, NAVA would reduce severe patient-ventilator asynchrony during NIV in selected hypoxemic patients with ARF.

**Materials and Methods**

This study was performed in the ICU of the Estaing Hospital (University of Clermont-Ferrand, France) from July 2011 to September 2011. The Institutional Review Board (Comité de Protection des Personnes Sud-Est I, Clermont-Ferrand, France) approved the protocol (reference number 2010-A01197-32), and each patient or next of kin provided written informed consent. This study followed CONSORT recommendations regarding the report of randomized trials.

**Study Population and Experimental Protocol**

All consecutive patients with ARF admitted to the ICU were eligible if they had at least two of the following five criteria for initiation of NIV: (1) worsening of dyspnea in the previous 10 days in the presence of chronic respiratory failure, (2) respiratory rate > 25 cycles/min, (3) respiratory acidosis with pH < 7.35, (4) PaCO2 > 50 mm Hg, and (5) Pao2 < 50 mm Hg. Patients with any contraindication for the insertion of a nasogastric tube or any contraindication for the insertion of a nasogastric tube or any classic contraindication to NIV were excluded. A Servo-I ventilator (MAQUET Gmbh & Co KG), using NIV software to compensate for air leaks, was used to deliver PSV, and a dedicated module and software were used for NAVA. EAdi was obtained through a nasogastric tube with a multiple array of electrodes placed at the distal end (EAdi catheter; MAQUET Gmbh & Co KG). Correct positioning was established by use of dedicated software, and continuous gastric emptying was performed to limit gastric air insufflation, in line with standard practice during NIV in our institution.

All patients were examined in the semirecumbent position, and sedatives were not given during the measurements. After enrollment, each patient underwent two 30-min trials in random order and separated by a 30-min rest period. In each mode, NIV was applied using a nonventilated facemask (ResMed) that was fitted tight to the face to avoid air leaks, focusing on leaks around the nasogastric tube. Pressure support and NAVA levels were adjusted to achieve a tidal volume (Vt) of 6 to 8 mL/kg of ideal body weight. In the PSV mode, flow-trigger sensitivity was adjusted to the lowest possible level that allowed detection of minimal inspiratory effort and avoided auto-triggering. The EAdi trigger was set to a predetermined default value of 0.5 µV. In each mode, the airway pressure limit was set at 25 cm H2O. The physician set the positive end-expiratory pressure to 5 to 10 cm H2O and the FIO2 to the level needed to reach a peripheral oxygen saturation of at least 92% and maintained these settings throughout the experiment. The fastest rate of pressurization and an expiratory trigger threshold of 30% of peak inspiratory flow were used in PSV. A fixed cycle-off value of 70% of peak EAdi was set in NAVA.

**Data Acquisition and Measurements**

On admission, demographic data, cause of ARF, Sequential Organ Failure Assessment (SOFA) score, and standard hemodynamics and arterial blood gas (obtained from a radial artery catheter) were recorded. Arterial blood gas analysis (GEM Premier 3000 analyzer; Instrumentation Laboratory) was performed at the end of each ventilation period. Peripherial oxygen saturation was measured continuously using pulse oximetry.

Respiratory parameters (airway pressure and flow, inspiratory Vt [VtI], expiratory Vt [VtE], and respiratory rate) and EAdi were acquired from the ventilator through a RS232 interface at a sampling rate of 100 Hz, and were recorded using dedicated software (Servo-tracker V3.6.2; MAQUET Gmbh & Co KG). After stabilization, a 5-min period of each NIV trial was recorded and manually analyzed offline. The recordings were excluded if the EAdi signal was lost or if the ventilator automatically returned to PSV. In each trial, patient-ventilator asynchronies (ineffective efforts, auto-triggering, premature cycling, delayed cycling, and double triggering) were determined on EAdi, airway pressure, and flow signal. The number of each type of asynchrony, defined as the number of events per minute, was determined for each recording period by two investigators (S. J. and J. M. C.) who were blinded to all analyzed tracings. The asynchrony index (AI), in percentage, was calculated as described previously, and an AI > 10% was considered severe asynchrony. Time parameters were determined from the EAdi and flow signals. The neural inspiratory time (Tin), in milliseconds, was defined as the time from the beginning of the EAdi signal to its maximal value (EAdi max), in microvolts. The trigger delay (Td), in milliseconds, was defined as the time from the beginning of the EAdi signal to the beginning of the inspiratory flow. The inspiratory time in excess (Ttie), in milliseconds, was defined as the difference between the ventilator inspiratory pressurization time and the Tin. Leaks at the mask were computed using the equation, Leaks (%) = (VtI – Vte)/VtI X 100, and were averaged over the recording period. Each patient reported the intensity of respiratory discomfort immediately after the end of each NIV trial by use of a Visually Enlarged Numerical Rating Scale (from 0 [no discomfort] to 10 [maximal imaginable discomfort]).
Statistical Analysis

The primary end point was the difference in the AI obtained by PSV and NAVA. Power analysis indicated that a sample size of 12 was needed to demonstrate a 20% reduction in the AI between PSV and NAVA modes, with α and β risks of 0.05 and 0.20, respectively. The secondary end points were differences in each type of patient-ventilator asynchrony, patients with AI > 10%, time parameters (Tint, EAdi max, Texe, Td), and oxygenation.

The Kolmogorov-Smirnov test was used to assess normality. Normally distributed data are expressed as mean ± SD and non-normally distributed data are expressed as medians and interquartile range (IQR). Qualitative data are presented as absolute values or number of events (%). Data were analyzed using the paired Student t test or the Kruskal-Wallis H test, as appropriate. Post hoc analyses were performed with the Bonferroni correction when appropriate. A P value < .05 was considered significant. Data were analyzed using SEM software (version 2.0; Centre Jean Perrin).26

Results

Sixteen consecutive patients with ARF were enrolled initially. Three of these patients were excluded, two because a worsening of ARF required tracheal intubation, and one because of an inappropriate EAdi signal. A total of 13 patients completed the study protocol (Table 1). There was no patient with COPD. On admission, all patients needed oxygen therapy (mean Fio₂, 50% ± 26%).

Table 2 shows the ventilatory settings under PSV and NAVA. No relevant clinical problems occurred during any procedure, and none of the trials was stopped prematurely. During NAVA, no recording was excluded because of automatic reversion to PSV. The mean level of pressure support in PSV was 7 ± 2 cm H₂O, and the NAVA gain level was 0.6 cm H₂O/µV (IQR, 0.3-0.8). There were no significant differences between the two NIV trials in airway pressure, expired TV, or positive end-expiratory pressure (Table 3). There was also no difference in the magnitude of leaks between the two NIV trials (12.6% [IQR, 7-17] vs 14.2% [IQR, 6-19], P = .16, during NAVA and PSV, respectively).

Table 3 shows the respiratory parameters and patient-ventilator asynchrony for the two NIV trials. Ineffective efforts and delayed cycling were the most common forms of asynchronies, and these were significantly more common under PSV (Table 3). There were no differences in autotriggering, double triggering, or premature cycling. The EAdi max, Td, and Texe were significantly lower during NAVA than during PSV (Table 3).

The AI was 60% ± 30% lower during NAVA than during PSV (Fig 1). In addition, the number of patients with severe asynchrony (AI > 10%) was significantly higher during PSV than during NAVA (48% vs 8%, P = .027). There were also fewer total asynchronies during NAVA than during PSV (10 [IQR, 5-14] events vs 17 [IQR, 8-24] events, P = .017) (Fig 2).

Finally, Table 4 shows the arterial blood gases and hemodynamics during PSV and NAVA. Compared with baseline, PaO₂/Fio₂ was significantly higher during each NIV trial (P = .029 during PSV vs baseline and P = .001 during NAVA vs baseline) (Tables 1, 4), but there was no significant difference between PSV and NAVA (P = .62) (Table 4). In addition, patients reported no significant differences in the intensity of respiratory discomfort during PSV and NAVA (PSV, 5 [IQR, 4-6]; NAVA, 7 [IQR, 5-8]; P = .15).

Discussion

With respect to specific experimental conditions, the results of the current study indicate that the use of NAVA instead of PSV for NIV in patients with ARF improves patient-ventilator interaction. In particular,
NAVA delivered through a facemask improved patient-ventilator interaction by reducing the total number of asynchrony events, severe patient-ventilator asynchrony (AI > 10%), the Td, and Ti\textsubscript{exe}.

Our results agree with those of previous studies that showed that NAVA can improve patient-ventilator synchrony during NIV both in healthy subjects\textsuperscript{2} and in patients with postextubation failure.\textsuperscript{22} In contrast to previous studies, which used helmets, we used a facemask because facemasks are more common during acute clinical applications of NIV.\textsuperscript{2} In addition, use of a helmet is less efficient than use of a facemask in decreasing inspiratory effort and muscle unloading\textsuperscript{23} and is associated with greater patient-ventilator asynchrony during NIV.\textsuperscript{24} This might have led to an overestimate of the benefits of NAVA in a previous study by Cammarota et al.,\textsuperscript{22} in which a severe AI (> 10%) was documented in an average of 80% of patients during each PSV trial.

The most remarkable difference between NAVA and PSV was the reduction in the number of patient-ventilator asynchrony events, especially ineffective efforts. Ineffective triggering, in which the patient’s inspiratory effort fails to trigger the ventilator, is common during NIV\textsuperscript{9} and has been reported to increase the work of breathing.\textsuperscript{15} It is unlikely that excessive levels of assistance and leaks, which have been identified as important contributors to ineffective efforts,\textsuperscript{15,25} can explain our results. Indeed, we adjusted PSV levels to achieve a V\textsubscript{T} of 6 to 8 mL/kg, which is believed to limit overassistance.\textsuperscript{26} Moreover, because similar levels of airway pressure and TV were achieved during NAVA and PSV (Table 3), the levels of assistance were presumably equivalent.\textsuperscript{15} Interestingly, we also found that the Td was shorter during NAVA than during PSV. A dedicated NIV algorithm could correct for possible negative effects of air leaks on Td and pressurization,\textsuperscript{14,27} but a significant pneumographic signal is needed to initiate ventilator support in PSV, and a neural respiratory drive to the diaphragm is used in NAVA.\textsuperscript{9} Thus, our data are consistent with those of a recent study of intubated patients,\textsuperscript{9} although the use of an endotracheal tube does not allow direct comparison.

In contrast to previous data using helmets,\textsuperscript{22} our results indicated that delayed cycling and Ti\textsubscript{exe} were both better with NAVA and that Tm\textsubscript{n} was unchanged. The delivered pressure under NAVA is closely synchronized with diaphragmatic activity,\textsuperscript{7} but under
respiratory center activity promote overassistance, which, in turn, downregulates Prolonged mechanical infl ation beyond the T breathing.

It should be noted, however, that T\textsubscript{i}exes remains under NAVA, because the ventilator cycling-off criterion induces an inherent delay between the end of the T\textsubscript{i}n and the end of the assistance delivered.\textsuperscript{9} Prolonged mechanical inflation beyond the T\textsubscript{i}n can promote overassistance, which, in turn, downregulates respiratory center activity\textsuperscript{16} and increases the work of breathing.\textsuperscript{28}

EAdi max was higher under NAVA than under PSV, although peak pressure values and V\textsubscript{t} were not different between the two modes. This is contrary to the findings of previous studies of NIV.\textsuperscript{22} These differences may be due to the use of different types of interfaces and/or different patient selection criteria. Indeed, some previous studies examined patients who were on invasive ventilation for variable times, and this could have led to ventilator-induced diaphragmatic dysfunction that affected diaphragmatic effort in certain patients.\textsuperscript{29,30} Beck et al\textsuperscript{31} emphasized that EAdi accurately reflects changes in phrenic nerve activity and global diaphragm activation (i.e., respiratory drive) in patients with ARF, and that excessive assistance may be associated with a progressive neuromechanical uncoupling.\textsuperscript{33} Nevertheless, whether the use of NAVA can improve neuromechanical coupling of the diaphragm remained to determine.

Although NAVA requires the use of a nasogastric tube, which is usually not necessary for noninvasive PSV, our findings may be clinically relevant for patients with obstructive airway disease, whose T\textsubscript{i}exe and overinflation can exacerbate dynamic hyperinflation. NIV demonstrated good efficacy in reducing the risk of invasive ventilation and mortality during acute exacerbation of COPD,\textsuperscript{32} but patient-ventilator asynchrony may reduce NIV success.\textsuperscript{9} NAVA may also represent an attractive alternative to PSV when applying NIV for treatment of postoperative ARF,\textsuperscript{23} in particular after abdominal surgery, where the use of a nasogastric tube remains a common practice. Further well-powered and controlled trials are needed to better clarify the role of NAVA in these specific conditions.

The present study had several limitations. First, this was a physiologic study and was not designed to document patient outcome. Second, although our ventilator settings reflect usual clinical practice, our results should not be extrapolated outside this range of settings. Optimal NAVA level remains uncertain,\textsuperscript{32,35} and extension of our results to different clinical conditions requires further study. In addition, because the optimal flow cycling-off level may vary among individuals,\textsuperscript{36} the use of fixed, rather than individually optimized, criteria for inspiratory trigger with PSV (25%-30% of peak inspiratory flow) could have led to

\begin{table}
\centering
\caption{Arterial Blood Gases and Hemodynamics During PSV and NAVA}
\begin{tabular}{|l|l|l|l|}
\hline
Parameter & PSV (n = 13) & NAVA (n = 13) & P Value \\
\hline
pH & 7.46 (7.42-7.49) & 7.46 (7.41-7.48) & .74 \\
$P_{A}O_{2}/P_{FIO_{2}}$ & 287 (201-346) & 311 (245-347) & .62 \\
$P_{a}CO_{2}$ mm Hg & 39 (37-40) & 36 (34-38) & .15 \\
$HCO_{3}^{-}$, mmol/L & 26 (25-27) & 26 (25-28) & .66 \\
$SaO_{2}$, % & 98 (97-99) & 98 (97-99) & .61 \\
MAP, mm Hg & 93 ± 11 & 92 ± 17 & .95 \\
HR, beats/min & 85 ± 16 & 85 ± 14 & .74 \\
\hline
\end{tabular}
\textsuperscript{2} Data are presented as mean ± SD or median (interquartile range) according to their distribution. $HCO_{3}^{-}$ is serum bicarbonate; HR is heart rate; MAP = mean arterial pressure; $SaO_{2}$ = arterial saturation in oxygen. See Table 2 for expansion of other abbreviations.
overestimation of the difference between NAVA and PSV. Third, there was no patient with known COPD in the study population. A recent study demonstrated, however, that NAVA improved patient-ventilator interaction in intubated patients with COPD relative to that provided by PSV, especially when high ventilatory assist is used.10 Nevertheless, because COPD is somewhat specific, it is uncertain whether our results can be extended to this population. Fourth, as reported previously, we used a visual numeric rating scale rather than a visual analog scale to assess patient discomfort during NIV. Nevertheless, neither psychometric properties of self-report scales for patient discomfort during NIV, such as validity and performance, nor comparison between them, has been performed in this setting.

In conclusion, based on our specific experimental conditions, we found that, compared with PSV, NAVA limits severe patient-ventilator asynchrony and results in similar improvement in gas exchange during NIV in patients with ARF. Further studies are needed to determine whether the use of NAVA during NIV can improve patient outcome.
