8 **Summary**

9 The use of echosounder buoys deployed in conjunction with Drifting Fish Aggregating Devices  
10 (DFADs) has progressively increased in the tropical tuna purse seine fishery since 2010 as a  
11 means of improving fishing efficiency. Given the broad distribution of DFADs, the acoustic  
12 data provided by echosounder buoys can provide an alternative to the conventional CPUE index  
13 for deriving trends on tropical tuna stocks. This study aims to derive reliable indices of presence  
14 of tunas (and abundance) using echosounder buoy data. A novel methodology is presented  
15 which utilizes random forest classification to translate the acoustic backscatter from the buoys  
16 into metrics of tuna presence and abundance. Training datasets were constructed by cross-  
17 referencing acoustic data with logbook and observer data which reported activities on DFADs  
18 (tuna catches, new deployments and visits of DFADs) in the Atlantic and Indian Oceans from  
19 2013 to 2018. The analysis showed accuracies of 75 and 85 % for the recognition of the  
20 presence/absence of tuna aggregations under DFADs in the Atlantic and Indian Oceans,  
21 respectively. The acoustic data recorded at ocean-specific depths (6 – 45 m in the Atlantic and  
22 30 – 150 m in the Indian Ocean) and periods (4 am – 4 pm) were identified by the algorithm as  
23 the most important explanatory variables for detecting the presence of tuna. The classification  
24 of size categories of tuna aggregations showed a global accuracy of nearly 50% for both oceans.

25 This study constitutes a milestone towards the use of echosounder buoys data for scientific  
26 purposes, including the development of promising fisheries-independent indices of abundance  
27 for tropical tunas.

## 31 **1. Introduction**

32 Many marine species are known to naturally aggregate under floating objects. Although still  
33 poorly understood, this behaviour is widely exploited by fishermen, who deploy man-made  
34 floating objects (hereafter referred to as Fish Aggregating Devices or FADs) worldwide to  
35 improve their catches (Kakuma, 2001; Fonteneau et al., 2013; Albert et al., 2014). The use of  
36 drifting FADs (DFADs) in tropical tuna fisheries was first introduced in the late 1980s in the  
37 Eastern Pacific Ocean by the US purse seine fleet (Lennert-Cody and Hall, 2001) and was later  
38 extended to all oceans and fleets from the 1990s. The instrumentation of DFADs with GPS  
39 beacons and echosounder buoys, in the mid and late 2000s respectively (Lopez et al., 2014),  
40 led to major changes in fishing strategies and behaviour of purse-seine fleets (Torres-Irineo et  
41 al., 2014). By providing skippers with almost real-time remote information on the precise  
42 location of DFADs, and on the potential presence and size of the tuna aggregation, echosounder  
43 buoys reduced the search time between two successful DFAD sets (Lopez et al., 2014). As a  
44 result, modern DFADs have significantly increase fishing efficiency (Fonteneau et al., 2013).  
45 Consequently, their use has increased considerably in the past few decades. Recent studies  
46 indicate that in less than a decade, the number of DFADs deployed in the Atlantic and Indian  
47 Oceans have increased at least fourfold (Fonteneau et al., 2015; Maufroy et al., 2017). It is  
48 estimated that over half of the annual tropical tuna purse seine catch originate from fishing sets  
49 on DFADs (Dagorn et al., 2013; Fonteneau et al., 2013).

50 Aside from being highly efficient fishing tools, the large number and vast spatial distribution  
51 of DFADs, coupled with their constantly evolving technology (Lopez et al., 2014), mean that  
52 they can also potentially provide unprecedented scientific insights into pelagic communities  
53 (Moreno et al., 2016; Brehmer et al., 2018). The echosounder buoys attached to DFADs  
54 regularly produce and transmit biomass estimation data. This dataset potentially holds a major  
55 opportunity for improving the management of tropical tuna stocks through the development of

56 fishery-independent abundance indices (Capello et al., 2016; Santiago et al., 2016). Currently,  
57 the main abundance indicators used in stock assessment for tropical tunas are derived through  
58 the standardization of Catch per Unit of Effort (CPUE) from commercial data (Fonteneau et al.,  
59 1998; Maunder et al., 2006). However, owing to the constant technological advances occurring  
60 in the purse seine fishery, it is extremely difficult to accurately standardize the CPUE time-  
61 series (Fonteneau et al., 1999). Traditionally, search time was used to quantify normal fishing  
62 effort in this fishery, however, owing to its non-random nature, the DFAD-based fishery has  
63 made this metric inconsistent over time, thus introducing major biases and uncertainties in the  
64 relationship between tuna catches and abundance (Fonteneau et al., 1999; Gaertner et al., 2015).

65 The need for the consideration of non-traditional data sources to provide alternate abundance  
66 indices for stock assessment of tunas is becoming increasingly apparent. In this regard, the large  
67 amount of acoustic data autonomously collected by commercial echosounder buoys on DFADs  
68 is of undeniable value. However, the direct exploitation of these data remains challenging. The  
69 biomass estimate that a buoy produces is limited by the reliability and variability of the  
70 information provided, which depends on the hardware and software characteristics of the buoy,  
71 and varies between manufacturers (Lopez et al., 2014; Santiago et al., 2016). As a result, the  
72 data provided by echosounder buoys are heterogeneous in types and formats, with limited  
73 studies having provided an assessment of their accuracy for use in scientific investigations.  
74 (Lopez et al., 2016; Baidai et al., 2017; Orue et al., 2019a).

75 In recent years, fisheries scientists have shown a growing interest in machine learning methods  
76 for the processing of both passive acoustic data (Roch et al., 2008; Zaugg et al., 2010; Noda et  
77 al., 2016; Malfante et al., 2018) and acoustic data collected by scientific echosounders  
78 (Fernandes, 2009; Robotham et al., 2010; Bosch et al., 2013). Despite this trend, very few  
79 studies have been conducted on the implementation of automated classification methods for  
80 analysing the extensive datasets collected by commercial vessels (Uranga et al., 2017).

81 This paper presents a new methodology, based on machine learning, for processing the  
82 echosounder data collected from one of the main models of echosounder buoy used to equip  
83 DFADs worldwide (Moreno et al., 2019).

## 84 **2. Material and Methods**

### 85 *2.1. Database description*

#### 86 2.1.1. Echosounder buoy data

87 We used data from the Marine Instruments M3I buoy (<https://www.marineinstruments.es>),  
88 collected on DFADs deployed by the French purse seine vessels operating in the Western Indian  
89 and Eastern Atlantic oceans from 2013 to 2018. The dataset consists of more than 60 million  
90 data points collected by approximately 35 000 M3I buoys. This model of buoy includes a solar  
91 powered echosounder operating at a frequency of 50 kHz, with a power output of 500 W, a  
92 beam angle of 36°, and a sampling frequency of 5 minutes (Fig. 1A). The acoustic data are  
93 processed by an internal module that automatically converts the acoustic energy into (i) a total  
94 biomass index and (ii) 50 integer acoustic scores (ranging from 0 to 7) indicating the acoustic  
95 energy recorded within 3 m depth layers, over a total detection range of 150 meters (Fig. 1B).  
96 In the default-operating mode, the internal module stores the 50 acoustic scores that correspond  
97 to the highest total biomass index recorded every 2 hours. From here on these 50 acoustic scores  
98 will be referred to as an “acoustic sample”. The assessment of the accuracy of the total biomass  
99 index calculated directly by the buoy’s internal module is presented in the Supplementary  
100 Appendix A1. The set of acoustic scores which constitute the acoustic sample is transmitted via  
101 satellite to the purse seine vessel every 12 hours under default settings. During the satellite  
102 communication, the GPS position of the buoy is also recorded and transmitted.

### 103 2.1.2 Activity data on DFADs

104 To ground truth the echosounder buoy dataset, catch and fishing activities were obtained from  
105 fishing logbooks of purse seine vessels and on-board observer reports from 2013 to 2018 in the  
106 western Indian and eastern Atlantic oceans. Observer data were collected under the EU Data  
107 Collection Framework (DCF) and the French OCUP program (Observateur Commun Unique  
108 et Permanent), which reached a coverage rate of 100% in the Atlantic Ocean in 2015 (Goujon  
109 et al., 2018), and over 80% since 2016, in the Indian Ocean (Goujon et al., 2017). From this  
110 combined dataset, the date, time, GPS location and buoy identification code associated with (i)  
111 fishing sets, (ii) newly deployed DFADs and (iii) visits to DFADs equipped with buoys owned  
112 by the vessel and which did not result in a fishing operation, were selected to be cross-  
113 referenced with echosounder buoy dataset. For successful fishing sets on DFADs, catch data  
114 for the three primary target species; yellowfin (*Thunnus albacares*), bigeye (*Thunnus obesus*)  
115 and skipjack tuna (*Katsuwonus pelamis*) were also considered. These catch data were used to  
116 ground truth the buoy's ability to detect the presence and size of tuna aggregations, assuming  
117 that the entire fish aggregation is encircled and captured by the fishing vessel. Conversely,  
118 newly deployed DFADs and visits to DFADs that did not result in any catch were used to  
119 ground truth the buoy's ability of detecting the absence of a tuna aggregation. For this  
120 assessment, DFAD deployments and visits where fishing sets were reported within the  
121 following week were omitted, to ensure that the data truly represented the absence of tuna at  
122 the DFADs. Similarly, only the deployments of new DFADs were considered and all other  
123 deployment operations were discarded (e.g., reinforcement of an existing DFAD, deployment  
124 of a buoy on a natural log).

125 Skunk fishing sets (sets where the tuna school totally or partially escaped) and activities, for  
126 which the reported set position was inconsistent with the position reported by the buoy, were  
127 removed. Only data for which the buoy identification code corresponded to a buoy code present

128 in the echosounder buoy database were retained in the analysis. The final database used for  
129 each activity and ocean is described in Table 1.

## 130 2.2. Acoustic data pre-processing

131 Daily acoustic data provided by an individual buoy consists of a  $50 \times N$  matrix  $S$ , where 50  
132 represents the number of depth layers and  $N$  corresponds to the number of acoustic samples  
133 provided for that day according to the operating mode of the buoy (in the default operating  
134 mode, the acoustic scores are stored every 2 hours, thus  $N=12$ ). Elements of the matrix  $S$   
135 correspond to the daily acoustic scores  $S_{ij}$  (i.e., integers ranging between 0 and 7) recorded at  
136 different depth layers  $i$  ( $i=1, 50$ ) and different times of the day  $j$  ( $j=1, N$ ). In a pre-processing  
137 step, the temporal and spatial information was aggregated to standardize the data and achieve a  
138 reduction in dimensions as follows:

139 (1) the acoustic scores of the two shallowest layers (0 – 6 m depth), representing the transducer  
140 near-field, were removed, leading to a  $48 \times N$  matrix;

141 (2) for each layer  $i$ , the daily acoustic scores  $S_{ij}$  were averaged over 4-hours periods, resulting  
142 in a reduced matrix  $S'$  of  $48 \times 6$  (Fig. 2);

143 (3) a clustering method was applied on  $S'$  along the dimension  $i$ , to identify homogeneous  
144 groups of depth layers. The clustering method was based on a dissimilarity matrix computed  
145 from Euclidean distance and Ward's method (Murtagh and Legendre, 2014). The acoustic  
146 scores in each identified group were compared through a Kruskal-Wallis test<sup>1</sup>;

147 (4) for each homogeneous group  $G$ , the acoustic scores recorded previously for each of the  $i$   
148 depth layers constituting the group were summed and rescaled to obtain a unique score ( $S''_{Gj}$ )  
149 per group  $G$  and time period  $j$ , according to Eq. 1.

---

<sup>1</sup> Clustering analyses were conducted using the R function “*hclust*” (R Core Team, 2019), and the Kruskal-Wallis test with the R function “*kruskal.test*”

150 
$$S''_{Gj} = \frac{\sum_{i=1}^{n_G} S'_{ij}}{\text{maxs} \times n_G} \quad (1)$$

151 where  $j$  denotes the 4-hours time period,  $n_G$  the number of depth layers belonging to group  $G$   
 152 and  $\text{maxs}$  is a constant denoting the maximum score (7 in the case of M3I buoys). The result of  
 153 the pre-processing step leads to a  $N_G \times 6$  matrix  $S''$  (i.e.,  $N_G$  groups of layers  $\times$  6 four-hour  
 154 periods recorded during a day), summarizing the acoustic information collected on a daily scale,  
 155 and referred to hereafter as a “daily acoustic matrix” (Fig. 2).

## 156 2.3. Supervised learning classification

### 157 2.3.1. Training dataset

158 The training datasets were constructed by cross-matching activity data (catch, deployments,  
 159 visits without fishing sets) with the daily acoustic matrices, using buoy identification codes,  
 160 dates and times for each ocean. A first binary training dataset was constructed for describing  
 161 the presence or absence of tuna, in which catch events corresponded to tuna presence and  
 162 deployment and visits without catch, to the absence of tuna (see Table 2). A second multiclass  
 163 training dataset was created for describing the size of the tuna aggregation. The catch data were  
 164 divided into three classes:  $< 10$  tons,  $10 - 25$  tons,  $>25$  tons, based on the total catch of the set  
 165 (i.e., the sum of the catch of the three target tuna species: yellowfin tuna, bigeye tuna and  
 166 skipjack tuna). The number and limits of the size classes were selected in order to retain a  
 167 sufficient and balanced number of data points in each class for the learning process, while also  
 168 maintaining consistency with the catch data. Class limits were based on the first quantile (10  
 169 tons) and the average (25 tons) of catches under DFADs in the dataset (see Table 3).

170 The daily acoustic matrices of tuna presence were constructed using the acoustic data recorded  
 171 the day before catch events. Similarly, the daily acoustic matrices corresponding to tuna  
 172 absence were selected from the daily acoustic matrices obtained the day prior to DFAD visits

173 without fishing sets, and those obtained on the fifth day after new DFAD deployments. The  
174 rationale for considering these 5-day periods after deployment was to account for the acoustic  
175 signal produced by the non-tuna species. Prior studies (Deudero et al., 1999; Castro et al., 2002;  
176 Nelson, 2003; Moreno et al., 2007; Macusi et al., 2017) have indicated that the colonization of  
177 DFADs by non-tuna species occurs within a range of a few hours to one week after deployment.  
178 Furthermore, preliminary analyses conducted on 528 and 5868 newly deployed DFADs, in the  
179 eastern Atlantic and western Indian oceans respectively, indicated a rapid increase in the  
180 acoustic signal recorded by the buoys during the first five days following deployment  
181 (Supplementary Appendix A3: Fig. A3.1 and A3.2). After considering all of these reasons, we  
182 assumed that acoustic data recorded at this post deployment time-scale were more likely to  
183 represent the presence of non-tuna species under DFADs.

#### 184 2.3.2. Random forest algorithm

185 The random forest classification algorithm<sup>2</sup> (Breiman, 2001) was applied on an ocean-specific  
186 basis. Predictors were represented by daily acoustic matrix values. Three thousand trees were  
187 grown for each classification. This high value does not negatively impact the model's  
188 performance (Breiman, 2001), and helps to stabilize the importance of the variables more  
189 effectively (Liaw and Wiener, 2002; Probst et al., 2019). For each classification model, the  
190 number of variables randomly sampled as candidates at each split was assessed through a grid-  
191 search strategy implemented with the R package "caret" (Kuhn, 2008). In order to deal with the  
192 imbalanced number of observations in the different size categories a stratified down-sampling  
193 procedure, which consisted of resampling the dominant size categories to make their  
194 frequencies closer to the least common size category, was also applied (Kuhn and Johnson,  
195 2013).

---

<sup>2</sup> The random forest classification was performed by using the R package "randomForest" (Liaw and Wiener, 2002)

196 2.3.3. Model evaluation

197 The overall accuracy (i.e., the proportion of correct predictions) and the kappa coefficient  
198 (Cohen, 1968) were used to assess the overall performance of both binary and multi-size  
199 category classifications. Kappa coefficient is a reliability index estimated according to Eq. 2:

$$200 \quad \text{kappa} = \frac{\text{Pr}(a) - \text{Pr}(e)}{1 - \text{Pr}(e)} \quad (2)$$

201 where  $\text{Pr}(a)$  is the total proportion of agreement between the observed and predicted classes  
202 and  $\text{Pr}(e)$  is the theoretical proportion of agreement expected by chance. The closer this ratio  
203 is to 1, the better the classification performed.

204 In each classification, the conventional statistical measures of the performance of a binary  
205 classification test: sensitivity, specificity, and precision were evaluated from confusion  
206 matrices, using Eq. 3 - 5:

$$207 \quad \text{Sensitivity} = \frac{TP}{TP+FN} \quad (3)$$

$$208 \quad \text{Specificity} = \frac{TN}{FP+TN} \quad (4)$$

$$209 \quad \text{Precision} = \frac{TP}{TP+FP} \quad (5)$$

210 where for presence/absence classification,  $TP$  (true positive) and  $TN$  (true negative) are the  
211 proportions of presence (or absence) correctly classified;  $FN$  (false negative) and  $FP$  (false  
212 positive) are the proportions of absence (or presence) incorrectly predicted. For multiclass  
213 classification, positive cases correspond to the aggregation size category considered during the  
214 evaluation, while all other categories correspond to negative cases. Sensitivity (also known as  
215 recall or true positive rate) measures the efficiency of the algorithm in correctly classifying  
216 positive cases, and specificity (or true negative rate) measures the efficiency of the algorithm

217 in correctly classifying negative cases. Precision (or positive predictive value) is the fraction of  
218 correctly predicted presence among all tuna presence prediction.

219 The importance of the predictors in the classification process for each ocean was assessed  
220 through the analysis of the mean decrease in accuracy of the random forest model (i.e., the  
221 increase of prediction error after permuting each variable while all others remained unchanged  
222 during the tree construction; Breiman, 2001). Model training and evaluation were performed  
223 through a hold-out validation method which was repeated ten times. In each of the ten replicates,  
224 the original dataset was divided into two subsets: the training set and the validation dataset  
225 (representing 75% and 25% of the initial data, respectively).

## 226 **3. Results**

### 227 *3.1. Pre-processing of sampled depth layers*

228 The clustering analysis carried out on the 3 m depth layers led in both oceans to the formation  
229 of six groups with similar layer compositions between the two oceans (Fig. 3). In each ocean,  
230 the comparison of the acoustic scores between the identified groups showed highly significant  
231 differences (*p-value* at Kruskal-Wallis test < 0.001 for both Indian and Atlantic Oceans). Scores  
232 declined strongly with depth (Fig. 4). The deepest group of layers (which also aggregated the  
233 greatest number of layers), exhibited the lowest acoustic values, with averages close to zero  
234 (Fig. 4).

### 235 *3.2. Presence/absence classification*

236 The random forest algorithm performed well in discriminating between the presence and  
237 absence of tuna, with an overall accuracy of 75 and 85% in the Atlantic and Indian oceans,  
238 respectively (Table 4). In the Atlantic Ocean, the classification model was effective in detecting  
239 DFAD aggregations with tuna (sensitivity of 0.83), but exhibited a notable level of false

240 positives (specificity of 0.67). In the Indian Ocean the opposite trend was observed with the  
241 classification of tuna presence performing well (sensitivity of 0.81) and the detection of their  
242 absence also producing reliable results (specificity of 0.90).

### 243 *3.3. Classification of aggregation sizes*

244 The classification of aggregations into size classes was considerably less efficient than the  
245 presence-absence classification, with low overall accuracies (48 and 47 %) observed for the  
246 Atlantic and the Indian Oceans, respectively (Table 5). In the Atlantic Ocean, the highest  
247 proportion of misclassification was observed in the 10 – 25 tons category (precision of 0.22),  
248 whereas tuna schools below 10 tons and above 25 tons both performed similarly (precision of  
249 0.32 and 0.28 respectively). In the Indian Ocean, tuna schools over 25 tons and below 10 tons  
250 were also the most reliably detected aggregation size classes (precision of 0.44 and 0.42  
251 respectively); while intermediate aggregation sizes (10 – 25 tons) were successfully classified  
252 less regularly (precision of 0.35).

### 253 *3.4. Predictor importance*

254 For both binary and multiclass classifications, the importance of the acoustic predictors in the  
255 classification process showed strong ocean-specific patterns. In the Atlantic Ocean, the  
256 detection of tunas was principally driven by acoustic data recorded from 6 m to 45 m (Fig. 5A  
257 and 6A). Conversely, in the Indian Ocean, the main predictors resulted from deeper layers (30  
258 m to 150 m, Figure 5B and 6B). In these depth ranges, acoustic data recorded during daytime  
259 (4 am - 4 pm) appeared to be the most significant for both oceans and across all types of  
260 classifications. It should, however, be noted that in the Atlantic Ocean, the binary classification  
261 produced a wider time window (0 to 4 pm) than in the Indian Ocean.

262

#### 263 **4. Discussion**

264 This study describes a new methodology for processing data collected by a commercial  
265 echosounder buoy commonly used in the DFAD purse seine fishery. The approach utilizes the  
266 acoustic scores (reflective of abundance) recorded at different depths and times of the day and  
267 combines data pre-processing procedures and machine learning algorithms to classify tropical  
268 tuna aggregations under DFADs. Although several models of echosounder buoys process data  
269 internally and generate abundance indices for tuna, previous studies have shown that such  
270 information can be unreliable (Lopez et al., 2014, 2016). This could explain why most purse  
271 seine skippers pay little attention to this information. Rather than relying solely on these  
272 processed outputs, skippers tend to combine the acoustic information recorded at specific  
273 depths and times with their empirical knowledge and the oceanographic characteristics of the  
274 region to assist their decision making.

275 Working on a different brand of buoy, Lopez et al. (2016) developed the first approach to  
276 improve biomass estimations from data collected by echosounder buoys. These authors  
277 suggested that the acoustic signal collected during sunrise (i.e., when tuna are generally the  
278 most tightly concentrated under DFADs), should be considered for processing and assumed the  
279 structure of the aggregated biomass based on knowledge of the vertical behaviour of species  
280 under floating objects. Under this assumption, they suggested a vertical segregation between  
281 the species that make up the multispecific aggregation under DFADs (non-tuna species [3 – 25  
282 m], small tunas [25 – 80 m] and large tunas [80 – 115 m]), and applied an echo-integration  
283 procedure to convert the acoustic signal from each depth layer into biomass estimates using  
284 specific values of target strength and individual average weight for each group. The application  
285 of this approach to a larger dataset in the Indian Ocean (287 fishing sets) by Orue et al (2019)  
286 was found to be less effective than expected, and potentially affected by the large spatio-

287 temporal variability between oceanic regions which skewed the main assumptions that underlie  
288 the approach.

289 The methodology used by this study did not make any assumptions regarding the vertical and  
290 temporal distribution of tuna at DFADs. Using a supervised learning algorithm, this  
291 methodology mimics the learning process of the fishers on how they interpret the acoustic  
292 scores based on their experience. The training dataset used for this purpose utilizes buoy data,  
293 which is considered to be ground-truthed. These ground-truthed data have three underlying  
294 assumptions. The first assumption is that the tuna caught by a purse seine vessel around a DFAD  
295 represents all the tuna aggregated under that DFAD. This is typically the case, although it is  
296 possible that some tuna escape during the fishing procedure, such events are considered to be  
297 minor (Muir et al., 2012). In exceptional situations when very large fishing sets are made (>  
298 200 t), the skipper may decide to retain only part of the aggregation to avoid damaging the net.  
299 The second assumption is that tunas do not immediately associate with newly deployed DFADs.  
300 Although Orue et al. (2019b) indicated that tuna may arrive first under DFADs, previous studies  
301 (Deudero et al., 1999; Castro et al., 2002; Nelson, 2003; Macusi et al., 2017), including  
302 interviews with fishers (Moreno et al., 2007) suggested otherwise. In this study, the daily  
303 acoustic matrix recorded five days after the deployment of a new DFAD was used to represent  
304 the absence of tuna. It would be useful to develop dedicated studies that would aid in the  
305 understanding of the aggregation process of tuna and non-tuna species around DFADs. Finally,  
306 the third assumption considered that a purse seine vessel visiting its own DFAD (DFAD  
307 equipped with the vessel's buoy) without fishing also represents the absence of a tuna  
308 aggregation at the DFAD. It may be countered that a skipper could decide not to set on a DFAD  
309 when the vessel is already full, but this is an extremely rare event. External factors (e.g. strong  
310 currents) may also impede the fishing operations. However, if a vessel heads towards a DFAD  
311 that it owns, it is fair to assume that this would result in a fishing set (if tunas are present).

312 Furthermore, in an effort to avoid any bias associated with the external factors that could  
313 influence the skipper's decision, only DFAD visits that were not followed by a fishing set within  
314 seven days were taken into consideration. Our decision to include visits without fishing  
315 operations in the training database as "absence of tuna" was taken based on numerous  
316 discussions with skippers. According to many of them, it is not uncommon that the echosounder  
317 buoys report high levels of acoustic energy even if tuna are absent from the aggregation. The  
318 objective of including these DFAD visits in the database was to improve the ability of the  
319 classification model to detect such false positives.

320 The results from this study highlight the effectiveness of the proposed methodology for  
321 discriminating between the presence and absence of tuna aggregations under DFADs equipped  
322 with M3I buoys in both the Indian and Atlantic oceans. To date the reliability of this model of  
323 buoy in estimating the presence and size of tuna aggregations had only been assessed  
324 anecdotally based on opinion and feedback from skippers. The development of reliable methods  
325 for processing data provided by commercial echosounder buoys represents a key step in the use  
326 of these fishing tools for scientific purposes, particularly the study of the different aspects of  
327 the ecology and behaviour of tuna associated with floating objects. The algorithm's lower  
328 performance in the Atlantic Ocean, where a higher proportion of false positive predictions of  
329 tuna presence were generated, could well be related to the size of the training dataset. In the  
330 Atlantic Ocean, this dataset was 5.5 times smaller than that used for the India Ocean. However,  
331 this difference may also reflect an ocean-specific vertical distribution of fish aggregations under  
332 DFADs. In the Indian Ocean, previous studies have described a vertical segregation between  
333 tuna and non-tuna species (Forget et al., 2015; Macusi et al., 2017). Such segregation would  
334 result in the determination of an absence of tuna to be straightforward for the classification  
335 algorithm. To date no studies have investigated the vertical distribution of tuna and non-tuna  
336 species under DFADs in the Atlantic Ocean. The depth of the thermocline in the eastern Atlantic

337 Ocean is known to be shallower than in the western Indian Ocean (Schott et al., 2009; Xie and  
338 Carton, 2013). This difference may result in tunas occupying shallower depths and thus mixing  
339 more regularly with non-tuna species. Such a phenomenon could provide an explanation for the  
340 higher rates of false positives generated in the Atlantic Ocean (i.e., false detection of the  
341 presence of tuna). The analysis of the relevance of the predictive factors in the random forest  
342 classifications showed that, for both oceans, daytime periods were the most relevant factor for  
343 distinguishing the presence of tuna schools from other acoustic targets. This result is likely  
344 linked to the behaviour of tuna schools and their spatial and temporal distribution around  
345 DFADs. Sonar surveys conducted on DFADs in the Indian Ocean revealed that tuna form a  
346 large number of small and dispersed schools during the night, and few and larger schools during  
347 daytime (Trygonis et al., 2016). Another possible reason could be related to the influence of the  
348 diel vertical migration of the deep scattering layer to the near surface at night (Robinson and  
349 Goómez-Gutierrez, 1998), which may affect the acoustic signal.

350 In both oceans, the performance of the classification algorithm for discriminating between  
351 different aggregation sizes was considerably less satisfactory than the presence/absence of  
352 tunas. There are several possible explanations for these limitations. One potential source of bias  
353 may stem from the differing species composition considered in each size class. Due to skipjack  
354 tuna lacking a swim bladder, their acoustic response is very different from that of yellowfin or  
355 bigeye tuna (Josse and Bertrand 2000; Boyra et al. 2018), as such an aggregation of a given size  
356 would result in different acoustic signatures depending on the percentage of each species that  
357 make it up. Another source of bias could be linked to the position of the tuna aggregation in  
358 relation to the area that is sampled by the buoy (detection cone). Depending on the size of the  
359 aggregation and the behaviour of tuna around the DFAD, it is likely that the buoy's acoustic  
360 cone only detects part of the tuna aggregation, especially at shallow depths. Some  
361 environmental factors could also affect both the acoustic signal detection and fish behaviour,

362 and could thus have an effect on the classification of the aggregation size. Water temperature,  
363 for example, is known to have an effect on both the acoustic signal (Bamber and Hill, 1979;  
364 Straube and Arthur, 1994) and the abundance of tuna (Boyce et al., 2008). As such, the  
365 interpretation of buoy data, particularly concerning the accurate estimation of the aggregated  
366 biomass, may be strongly influenced by area and season-specific factors. In addition, close  
367 examination of the scores in the layer groups identified by the cluster analysis also revealed that  
368 layers deeper than 50 m were characterized by very low scores (Fig. 4). Previous studies on the  
369 vertical distribution of fish species under DFADs found that tuna regularly occurred below this  
370 depth (Dagorn et al. 2007a; Dagorn et al. 2007b; Forget et al. 2015; Matsumoto et al. 2016;  
371 Lopez et al., 2017). Consequently, it appears fair to assume that the low values obtained for  
372 these depths are likely related to the limited detection capability of the device at such depths,  
373 which may also explain the poor estimates of the size of the tuna schools.

374 The principle findings of this work showed that machine learning offers promising pathways  
375 for processing acoustic data provided by commercial echosounder buoys. Although this work  
376 has focused on a single model of buoy, it can easily be expanded to encompass other models  
377 and brands. The only essential requirement is access to a large training database.

## 378 **5. Conclusion**

379 The methodology developed in this study provides an indicator of presence/absence of tuna  
380 schools at DFADs in both the Atlantic and Indian Oceans, from simplified acoustic data  
381 collected by one of the echosounder buoy models used in the tuna purse seine fishery. This  
382 approach has the potential to summarize and analyse a large amount of acoustic data, with an  
383 efficiency that obviously depends on the nature and quality of the data provided. Nevertheless,  
384 the rapid and continuous evolution in echosounder buoys technology observed since their  
385 introduction is likely to provide, over time, better and more detailed data, leading to a

386 substantial improvement in the performance of the proposed methodology, specifically  
387 regarding assessment of aggregation sizes under DFADs. Applying this approach to other  
388 echosounder buoy models, like new multi-frequency buoy models, widely adopted in recent  
389 years, could also allow to assess and compare buoy reliabilities. Finally, although the  
390 availability of more extensive databases (with matched acoustic and catch data) and more  
391 detailed acoustic data (beyond the discrete 0 – 7 acoustic indices) could improve this  
392 methodology, the accurate discrimination between the presence and absence of tuna schools  
393 around DFADs obtained in this study constitutes a critical step towards the exploitation of  
394 echosounder buoy data for providing novel and robust indicators of abundance for the  
395 management of FAD fisheries in years to come.

## 396 **6. Acknowledgements**

397 This project was co-funded by “Observatoire des Ecosystèmes Pélagiques Tropicaux exploités”  
398 (Ob7) from IRD/MARBEC and by the ANR project BLUEMED (ANR-14-ACHN-0002). The  
399 authors are grateful to ORTHONGEL and its contracting parties (CFTO, SAPMER,  
400 SAUPIQUET) for providing the echosounder buoys data. The authors also thank all the  
401 skippers who gave their time to share their experience and knowledge on the echosounder  
402 buoys. The authors sincerely thank the contribution of the staff of the Ob7 for their work on the  
403 databases of the echosounder buoys and observer data. We are also sincerely grateful to the  
404 buoy manufacturers for their useful advice and information on their echosounder buoys.

617 **Tables**

618 Table 1: Number of fishing sets (with catch  $\geq 1$  ton), visit and deployment data collected from  
 619 2013-2018 and used in the presence-absence classification for the Atlantic and Indian Oceans.

	Atlantic Ocean			Indian Ocean		
	Catch	Visit	Deployment	Catch	Visit	Deployment
Logbook	817	255	405	2918	1031	6722
Observers	151	0	228	513	0	2487
Total	968	255	633	3431	1031	9209

620

621 Table 2: Structure of the training dataset used in the presence-absence and multiclass  
 622 classification for the Atlantic and Indian Oceans (over the period 2013-2018).

Ocean	No tuna	Tuna		
		< 10 tons	[10, 25 tons]	> 25 tons
Atlantic	888	397	303	268
Indian	10240	904	1288	1239

623

624 Table 3: Summary statistics of major tuna catches (in tons) from DFAD fishing operations  
 625 collected from observer and logbook databases from 2013 to 2018, in the Atlantic and Indian  
 626 Oceans. (Min. and Max. denote for minimum and maximum catch values, respectively. SD  
 627 represents standard deviation and Qu. stands for quantile)

Ocean	Min.	1 <sup>st</sup> Qu.	Median	Mean	3 <sup>rd</sup> Qu.	Max.	SD
Atlantic	1	6	15	22.61	30	177.70	25.59
Indian	1	10	20	26.73	34	300	26.77

628

629 Table 4: Summary of tuna presence/absence classification performances for the Atlantic and  
630 Indian Oceans: mean and standard deviation values (in brackets) of evaluation metrics.

Evaluation Metrics	Atlantic	Indian
Accuracy	0.75 (0.02)	0.85 (0.01)
Kappa	0.51 (0.04)	0.70 (0.02)
Sensitivity	0.83 (0.02)	0.81 (0.01)
Specificity	0.67 (0.03)	0.90 (0.01)
Precision	0.73 (0.03)	0.88 (0.01)

631

632 Table 5: Summary of multiclass classification performances for the Atlantic and Indian Ocean. Mean and standard deviation (in brackets) of  
 633 evaluation metrics

	Atlantic Ocean				Indian Ocean			
	No tuna	<10 tons	[10 , 25 tons]	> 25 tons	No tuna	<10 tons	[10 , 25 tons]	> 25 tons
Sensitivity	0.67 (0.03)	0.36 (0.05)	0.24 (0.08)	0.34 (0.06)	0.87 (0.03)	0.19 (0.01)	0.29 (0.02)	0.54 (0.04)
Specificity	0.82 (0.02)	0.80 (0.03)	0.84 (0.04)	0.85 (0.04)	0.80 (0.01)	0.91 (0.01)	0.82 (0.02)	0.77 (0.01)
Precision	0.77 (0.03)	0.32 (0.04)	0.22 (0.04)	0.28 (0.05)	0.59 (0.02)	0.42 (0.04)	0.35 (0.03)	0.44 (0.02)
Accuracy	0.48 (0.02)				0.47 (0.02)			
Kappa	0.26 (0.03)				0.30 (0.02)			

634

636

637 Fig. 1: Technical specifications of the Marine Instruments M3I echosounder buoy. (A): beam  
 638 width or cover angle (a), depth range (h), and diameter (D) at 150 m, (B): example of an acoustic  
 639 sample

640

641 Fig. 2 : Schematic view of the acoustic data pre-processing. (1) Temporal resolution reduction,  
 642 averaging acoustic samples over a 4-hour period. (2) Layer aggregation combining the 48  
 643 vertical layers into 6 layers based on cluster analysis. The final output is a 6x6 matrix  
 644 summarizing the acoustic signal recorded over 24 hours between 6 and 150 m. Acoustic scores

645 are integer values (ranging from 0 to 7), representing the intensity of the acoustic backscattered  
646 signal per 3 m depth layer. Time-aggregated acoustic scores represent the average value of the  
647 acoustic scores over the 4-hour interval. Group scores represent the sum of layer scores (scaled  
648 between 0 and 1) per homogeneous group of layers identified from the clustering analysis.

649

650

651 Fig. 3: Dendrogram from the cluster analysis of raw acoustic data for the Atlantic (A) and Indian  
652 (B) Oceans. The red horizontal line indicates the height at which the dendrogram was sliced to  
653 create the 6 groups of layers. Colors identify the different groups of depth layers used to pre-  
654 process the acoustic data.

655

656 Fig. 4: Boxplot of acoustic score values in the aggregated-layer groups identified by the cluster  
 657 analysis, for the Atlantic (A), and Indian (B) Oceans. Red diamonds represent mean value of  
 658 scores in each layer group.

659

660 Fig. 5: Importance of depth layers and day period in presence/absence classification for the  
 661 Atlantic (A) and Indian (B) Oceans. Each cell represents a combination of depth and time  
 662 period. Colours indicates the importance of the predictor in the classification.

663

664 Fig. 6: Importance of depth layers and day period in multiclass classification for the Atlantic  
 665 (A) and Indian (B) Oceans. Each cell represents a combination of depth and time period.  
 666 Colours indicates the importance of the predictor in the classification.
