31

32 **HIGHLIGHTS**

- 33 • Limitations in population growth of Peruvian sympatric otariid populations  
34 • Sea lions are the current ‘dominating’ otariid species in Peru  
35 • Decrease in juveniles contributes towards population decline  
36 • Resource partitioning between otariids needs to be further explored in Humboldt Current  
37 System

38

39 **ABSTRACT**

40 Sympatric species evolve mechanisms to avoid competition and coexist. In the Humboldt  
41 Current System (HCS), populations of South American sea lions (SASL, *Otaria byronia*) and  
42 South American fur seals (SAFS, *Arctocephalus australis*) fluctuate mostly due to ENSO events  
43 and prey availability. We evaluate population trajectories of Peruvian sympatric otariids and  
44 discuss mechanisms for competition and/or resource limitation. For this purpose, we analyzed  
45 population trajectories of SASL and SAFS in a sympatric breeding site in Punta San Juan, Peru  
46 between 2001-2019. Wavelet analysis was used to extract trends and derivatives to estimate rates  
47 and turning points. Age-class proportions and biomass times series were constructed from  
48 weekly counts and evaluated. Both populations show a growth phase and subsequent decline.  
49 SAFS started decline ~2.25 years before and at a rate 1.5 times faster than SASL. Decrease in  
50 juvenile age-class suggests that resource limitation is the main contributing factor for current  
51 population decline.

62

## 63 **1 INTRODUCTION**

64 Understanding how species coexist is an important theme in ecology. Coexistence theory is a  
65 framework to understand how competitor traits can maintain species diversity and prevent  
66 competitive exclusion, even among similar species in ecologically similar habitats (Chesson and  
67 Kuang, 2008). Competition can compromise the fitness of one of the species involved, and may  
68 ultimately lead to its exclusion (Pacala and Roughgarden, 1985). Under the resource-utilization  
69 niche concept, two species cannot occupy the same ecological niche without exerting strong  
70 competition on each other (Schoener, 1974). The Lotka–Volterra competition model states that  
71 coexistence of two species is possible when the competitive effect that a species has on another  
72 species (interspecific competition) is less than the competitive effect that it has on its own  
73 species (intraspecific competition) (Chase et al., 2002; Chesson and Warner, 1981; Schoener,  
74 1983). Furthermore, competitive interactions are known to be stronger between morphologically  
75 and phylogenetically closely related sympatric species (Di Bitetti et al., 2009; Loveridge and  
76 Macdonald, 2003; Schoener, 1983).

77

78 Otariids, composed of fur seals and sea lions, occur in sympatry in a number of upwelling  
79 regions in the world and have many similar life-history traits and foraging habits (Bailleul et al.,  
80 2005; Dellinger and Trillmich, 1999; Franco-Trecu et al., 2012; Jeglinski et al., 2013; Page et al.,  
81 2005; Villegas-Amtmann et al., 2013; Waite et al., 2012). Coexisting species are expected to  
82 develop strategies for niche differentiation when resources become scarce, to mitigate the  
83 reduction in population attributes, such as growth, survival or fecundity (Begon et al., 2006). The  
84 duration of coexistence in sympatric otariid seals is not known, and it is possible that sympatry  
85 has resulted from recent population recoveries posterior to the period of commercial sealing  
86 (Arnould and Costa, 2006). If sympatry is a result of recent events, it is possible that divergence  
87 is not yet evident or that competitive exclusion is now occurring.

88

89 In sympatric fur seals and sea lions, past research have found mixed results with regards to  
90 competition and segregation. Contrary to the situation in Peru, in many locations fur seal

91 populations are typically larger and they appear to outcompete sea lions (Wickens and York,  
92 1997). Researchers studying sympatric otariids have found trophic segregation, differing  
93 foraging strategies and contrasting population trends as mechanisms that explain coexistence  
94 (Franco-Trecu et al., 2014; Pablo-Rodríguez et al., 2016; Páez-Rosas et al., 2012). More recent  
95 studies demonstrate that intraspecific segregation, driven by interindividual specialization, takes  
96 place in colonial species (such as otariids) that are constrained to limited foraging ranges that  
97 overlap with conspecifics in similar niches (Jeglinski et al., 2013; Villegas-Amtmann et al.,  
98 2013; Schwarz et al., 2021).

99  
100 Some authors suggest that trophic segregation between sea lions and fur seals is associated with  
101 the observed divergent trends in epipelagic and benthic foraging characteristic of each group  
102 (Arnould and Costa, 2006) and argue that body size is a central feature that characterizes  
103 foraging modes between larger sized benthic foraging sea lions and smaller epipelagic foraging  
104 fur seals. In those studies, sea lions showed greater oxygen storage capabilities; enabling them to  
105 aerobically dive longer and deeper resulting in higher metabolic and reproductive outputs (Costa  
106 et al., 1998). However, other studies have also demonstrated that sea lions of different age-  
107 classes (Jeglinski et al., 2013; Villegas-Amtmann et al., 2013) and within the same age-class  
108 (Schwarz et al., 2021) display specialized types of benthic, pelagic and nocturnal epipelagic  
109 foraging. Other studies have shown that foraging modes can vary regionally in the same species,  
110 therefore demonstrating the importance of prey availability as a driver for foraging mode  
111 (Hückstädt et al., 2016).

112  
113 The Humboldt Current System (HCS) in Peru is recognized as the most productive of the Eastern  
114 Boundary Upwelling Systems in the world (Bakun and Weeks, 2008). As other upwelling  
115 ecosystems, cold nutrient rich water rises to the euphotic layer by a combination of the South  
116 east trade winds and the Coriolis force that fuel Ekman transport, giving rise to primary  
117 productivity in the upper pelagic and nearshore areas. Peru's coast is characterized by a narrow  
118 continental shelf, shallow productive upwelling waters and a relatively shallow thermocline  
119 related to an upper minimum oxygen layer at similar depths of approximately 50-80m, on  
120 average (Bertrand et al., 2010; Demarcq, 2009; Echevin et al., 2008). These features limit the

121 potential habitat for otariid prey to be linked to the benthos. Thus, in this productive shallow  
122 environment foraging on highly patchy, but dense prey resources near the surface, may preclude  
123 the advantages of searching for more evenly distributed, but less dense, prey resources on the  
124 benthos (Arnould and Costa, 2006), which are also constrained by bottom water hypoxia.

125

126 Furthermore, HCS is characterized by recurring El Niño Southern Oscillation (ENSO) events,  
127 which can vary in intensity and duration. ENSO is known as a cycle of alternating warm El Niño  
128 and cold La Niña events and is the most prominent climate signal on Earth (McPhaden et al.,  
129 2006). When HCS is affected by an ENSO, increments of sea surface temperature and reduction  
130 of primary productivity occur in the marine environment, altering distribution of habitats and  
131 associated prey biomass. The ENSO events that occurred in 1982-83 and 1997-98, were  
132 categorized as 'Extraordinary' and are well documented for dramatically altering species  
133 composition and reducing marine biomass (Barber and Chavez, 1983; Tam et al., 2008). These  
134 climatic signals were strong and felt worldwide, changing the availability of prey items and  
135 causing declines in reproduction and survival of top marine predator populations around the  
136 globe (Arias-Schreiber and Rivas, 1998; Bond and Lavers, 2014; Cárdenas-Alayza, 2012;  
137 Forcada et al., 2006; Oliveira et al., 2006; Sprogis et al., 2018; Trathan et al., 2007).

138

139 In Peru two species of otariids coexist that have breeding colonies along the coast, the South  
140 American sea lion (SASL) and South American fur seal (SAFS). Analysis of population trends  
141 of coexisting species helps understand population status and response to ecosystem conditions.  
142 Otariid surveys for the coast of Peru exist from mid 1960s, providing information on the  
143 abundance of these populations, but had heterogeneous sampling effort. Since the mid 1990s,  
144 systematic annual surveys are conducted at main colonies and during each species breeding  
145 season (February/March for SASL and November/December for SAFS) by scientists from  
146 Instituto del Mar del Peru (IMARPE) to monitor their status and fluctuations (Arias-Schreiber  
147 and Rivas, 1998; Oliveira et al., 2006). Regardless, variability in Peru otariid continues to be  
148 observed (Figure 1). In the 1970s and early 1980s, historical records show a similar abundance  
149 for SASL and SAFS of ~ 20-25,000 individuals. However, in the late 1980s and 1990s SASL  
150 were more numerous than SAFS. Furthermore, a decline of 75% and 80% is documented for

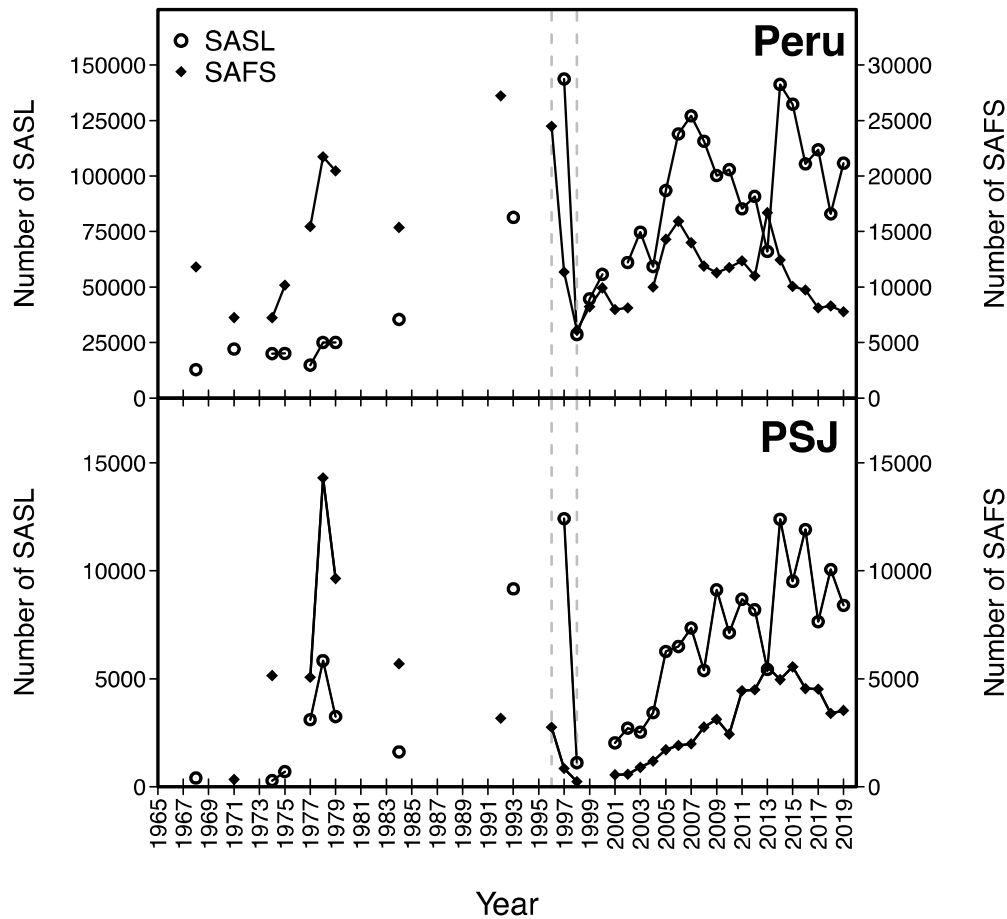

151 both SAFS and SASL, respectively due to the 1997-98 ENSO (Oliveira et al., 2006, 2012).  
152 Surveys post ENSO reflect population recoveries for both species but with a larger SASL  
153 abundance. Similar fluctuations are observed until 2014, after which, there is a decline in SAFS.  
154

155 Existence of sympatric colonies of SAFS and SASL implies that some mechanism currently  
156 operates (or has in the past), to permit interspecific coexistence in the HCS ecosystem. Sympatry  
157 of SAFS and SASL occur at only a few locations along the distribution ranges of our study  
158 species in the HCS. Punta San Juan (PSJ), a peninsula on the south coast of Peru is a sympatric  
159 site and is considered a historically important breeding center for otariids in Peru. The effects of  
160 the 1997-98 ENSO also impacted this breeding site, with local reductions of ~87% in both  
161 species. In PSJ, abundance declined from 2,751 to 345 in SAFS from November 1996 to  
162 November 1999 and from 12,415 to 1,495 in February 1997 to February 1999 in SASL (Arias-  
163 Schreiber and Rivas, 1998). Since the decline, weekly counts of otariids were conducted to  
164 monitor population recovery. Although high resolution time series of marine megafauna  
165 populations are scarce; at this location, weekly counts permit to study fluctuations in abundance,  
166 which can help understand interspecific and intraspecific interactions in a common ecological  
167 context. Thus, we consider that the long time series collected at PSJ (which accounts roughly for  
168 10-50% of the total Peruvian populations in both species in this only site) provide an adequate  
169 setting to study the coexistence of SAFS and SASL and is representative of their dynamics in  
170 Peru.

171

172 The main goal of this study is to describe population trajectories over the last 20 years, in a  
173 sympatric otariid colony in Peru and secondly, to discuss mechanisms (e.g. competition and/or  
174 resource limitation), possibly explaining these trends. In terms of the population trajectories, we  
175 expect a first phase of fast population recovery post 1997-98 ENSO, followed by a subsequent  
176 stabilization in populations' size. Given the larger body size and population size of SASL on the  
177 coast of Peru we hypothesize that the abundance and biomass of SASL dominates over SAFS, in  
178 PSJ during our study period. By using a combination of abundance time series, age-class  
179 proportions and biomass time series within and between species, we consider this is a first step  
180 towards exploring if larger body mass (SASL), a proxy for higher consumption of prey

181 resources, can offer a greater competitive advantage in comparison to a smaller species (SAFS)  
 182 to sustain population abundance in a common environmental setting.

183  
 184 **Figure 1.** Time series of the total number South American sea lions (SASL, open circles) and  
 185 South American fur seals (SAFS, filled diamonds) counted on the coast of Peru (top) and Punta  
 186 San Juan study site (bottom) between 1965-2019. Dashed grey vertical lines delimit the  
 187 population decline caused by the 1997-98 ENSO. Time series were constructed with official  
 188 counts from surveys obtained from various sources (Arias-Schreiber and Rivas, 1998; IMARPE,  
 189 2018, 2017, 2016, 2015, 2014, 2013, 2012; Majluf and Trillmich, 1981; Muck and Fuentes,  
 190 1987; SERNANP, 2016; Tovar and Fuentes, 1984).

## 2 METHODS

### 2.1 Study site and data collection

Punta San Juan (15°22'S, 75°12'W) is a peninsula protected from land by a 1.2 km concrete wall that is part of a marine coastal national reserve system called 'Reserva Nacional Sistema de Islas, Islotes y Puntas Guaneras' (RNSIIPG, Spanish acronym). The PSJ coastline consists of 20 sites, which are beaches and coves all used for breeding and/or as haul-out sites by SASL and SAFS. In PSJ operates the Punta San Juan Program, a long-term research program that monitors otariid and seabird populations *in-situ*. Access to the PSJ Program database was granted for purpose of this study. At PSJ, land-based counts of accessible otariid sites are conducted at least once per week since 2001 to monitor population dynamics. For this study we accessed the count data during years 2001 to 2019, which have a minimum frequency of once per week. Counts took place between 0600-0900 hours by observers with 10x50 binoculars and tally counters on top of 8 – 30 meter cliffs overlooking otariid sites. Accessible sites are counted for total abundance and age-class categories, for each species. Gaps in count data occurred when roosting seabirds made it impossible to access the cliff-edge to view beaches and coves. More frequent counts available during the breeding seasons (January thru March for SASL and October thru December for SAFS) at selected breeding sites, were also included to enhance time series. Due to the long-term nature of this dataset (19 years), counters changed over time and beaches were counted by different observers. Standard error of the mean count between three simultaneous observers ranges between 3-4% for SAFS and 3-13% for SASL. Satellite images with 2.8m resolution (image courtesy of CNES/Airbus 31 October 2019 via Google Earth) were used to estimate the area of the main breeding sites for each species. SAFS main breeding site was estimated through *in-situ* measurements collected during low tide in 1999 when animal abundance was zero and used to validate use of satellite images. Finally, a time series of mean monthly density was estimated during the breeding season (January – March for SASL and October – December for SAFS) by dividing mean monthly number of otariids by the area of the site where animals were counted on land and reported as number of individuals per square meter (ind /m<sup>2</sup>).

## 224 2.2 Abundance time series

225

226 In otariid breeding sites, the ratios of age-classes change throughout the year. Most evident shifts  
227 occur during the breeding season when territorial males, adult females and pups increase and  
228 subadult males and juveniles decrease. Breeding season for SAFS and SASL last for  
229 approximately 3 months (SAFS: October – December; SASL: January - March). Early in the  
230 breeding season males arrive to compete and hold territories; subsequently females arrive to give  
231 birth and there is rise in female and pup numbers. Females generally stay with the pup for 5-13  
232 days, depending on the species. After females complete their post-partum fasting period, they  
233 will be at sea for varying periods and return to land to nurse the pup. Intra-annual dynamics in  
234 each species and age-class was examined (Appendix A). Due to the intra-annual dynamics due to  
235 breeding and non-breeding seasons as well as the long-term population fluctuations, we  
236 detrended the abundance time series with the goal to extract an annual trend of abundance for  
237 analysis and remove all the high-frequencies' signal in the data.

238

239 Total abundance for PSJ was estimated from the sum of all sites individually counted on a given  
240 date between 2001 and 2019, for each species. We verified that interannual dynamics of study  
241 sites was the same as dynamic of the sum of all sites. Because counts varied on a daily to weekly  
242 scale, these were linearly interpolated to generate a time series with an equal sampling interval of  
243 every 3 days. To detrend the abundance time series and be able to extract the values we used a  
244 wavelet trend decomposition with a “morlet” mother wavelet, since it overcomes the problems of  
245 non-stationarity in a time series by performing a local time-scale decomposition of the signal.  
246 This method gives the possibility to investigate the temporal evolution of a times series with  
247 different rhythmic components.

248

249 We identified the wavelength scale corresponding to one year using wavelet analysis in  
250 WaveletComp R package v. 1.1 to extract the trend of abundance for both species. To test the  
251 study hypothesis, the trend of abundance time series, density and ratios of abundance will be  
252 compared between both species. Increasing or decreasing phase of trends, were determined with  
253 first order derivatives. Turning points will permit to detect when the date of change in direction

254 of a species population trajectory occurred. Difference of first order derivatives was used to  
255 understand which species was increasing over the other.

256

### 257 **2.3 Age-class proportions**

258 Time series for the proportion of each age-class were constructed using counts available for the  
259 main breeding sites of PSJ for SASL and SAFS, respectively. For this, we selected data sets from  
260 the main breeding sites in PSJ that are exclusive to one of the two species year-round. Age-class  
261 counts from beach site S3 were collected for SAFS between November 2003 to December 2019  
262 (n = 977 observations). For SASL, there was a change in the beach site used to estimate age-  
263 classes in years 2012-2013 to improve the number of times the sea lion breeding site could be  
264 accessed over the year by observers. Therefore, we constructed a single time series combining  
265 counts from beach site S7.S8 for years 2003-2013 and beach N7 for years 2012-2019 (n = 666  
266 observations), including a mean proportion between the two sites for overlapping dates. The  
267 pattern in the proportions was inspected carefully to verify that age-classes did not vary abruptly  
268 due to site change.

269

270 Age-class categories for this study includes: pups, juveniles, adult females, subadult males and  
271 territorial males. These are based on the categories used in the field at PSJ for counting animals,  
272 based on distinguishable anatomical features and behaviors (Vaz-Ferreira and Ponce de León,  
273 1987). A 'juvenile' category was created in this study to group the 'yearling' (1 year old) and  
274 'immature' (2-5 years old) categories used in the field. To estimate age-class proportions we  
275 only used the dates that considered all the beforementioned categories. Median proportions and  
276 interquartile range (IQR) were estimated .

277

278 Mean mass  $\pm$  SD of otariids according to age classes were estimated using PSJ Program  
279 database. Mass was collected at PSJ between during otariid tagging and health assessment  
280 fieldwork that involved weighing live animals during the study period. Mass of adult age classes  
281 were collected during the breeding season while pupping was taking place. Meanwhile, pup mass  
282 was collected during pup round-ups, approximately 2 months after the peak of pupping occurs in  
283 each species (April for SASL and January for SAFS). Mass for the SAFS subadult male age-

284 class was obtained from the PSJ Program necropsy records of individuals that stranded dead in  
285 PSJ due to interactions with longline fisheries, and is reported here. These animals were  
286 confirmed to have died from interaction with fishing gear, carcasses were in good body condition  
287 and therefore we consider their mass accurately represents their age-class. The only records of  
288 mass for dead juveniles available in PSJ were in emaciated body condition, probably due to  
289 nutritional stress, thus we do not consider they represent mass of healthy live individuals.

290

291 If values for the mean mass of an age-class were not available from PSJ, these were obtained  
292 from literature from conspecific or similar sized age-class otariids. We used reported mass of  
293 juveniles (Hückstädt et al., 2016) and territorial males (George-Nascimento et al., 1985) SASL  
294 collected in Chile. To our knowledge, no published values exist for mass of juvenile SAFS in the  
295 Pacific Ocean and in the Atlantic, studies either report captive animals or small sample sizes (<5)  
296 for an class that represents many ages and high variance. We therefore applied the reported mass  
297 of conspecific Northern fur seals (*Callorhinus ursinus*) from a study involving live captures and  
298 grouped mass of animals of ages 1-2, 2-3, 3-4 and 4-5 years old for the juvenile age class (Baker  
299 et al., 1994).

300

301 To verify our hypothesis about body size, we tested for differences between mean mass of age-  
302 classes between species. To evaluate if there is a source of competition between age-classes  
303 during breeding and non-breeding season (e.g., overlap in the proportion of territorial males and  
304 adult females in non-breeding season) we tested for independence between the weighted age-  
305 class proportions (product of proportion and mean mass for each age-class) within each species  
306 and season. This was done by applying a t-test or Mann Whitney Wilcoxon Test ( $p < 0.05$ ) after  
307 verifying data distribution. Finally, we describe any shifts in the trends of age-class proportion  
308 time series to explain the mechanisms behind the population trajectory for each species.

309

#### 310 **2.4 Biomass times series**

311 Biomass time series were constructed for each species in tons (t) by calculating the product of  
312 the abundance time series trend, the median age-class proportion and the mean mass per age-  
313 class. A time series for total otariid biomass was created from the sum of the SASL and SAFS

314 biomass time series to determine the proportion of biomass that pertains to each species. To test  
315 our hypothesis, the percentages of each of the species biomass over time are used to describe  
316 interspecific competition and evaluate if SASL are dominating over SAFS. All analysis were  
317 done using R software version 3.6.2.

318

### 319 **3 RESULTS**

#### 320 **3.1 Abundance time series**

321 After removing high frequency signal from count data, annual trends of abundance were  
322 extracted for each species. This revealed population trajectories in PSJ that vary between a range  
323 of 829 - 4,550 individuals for SASL (Figure 2A) and 291 – 3,443 individuals for SAFS (Figure  
324 2B) between 2001 to 2019. During this study period mean density of individuals during breeding  
325 was  $0.40 \pm 0.23$  ind /m<sup>2</sup> for SASL (January-March) and  $0.12 \pm 0.08$  ind /m<sup>2</sup> for SAFS (October-  
326 December).

327

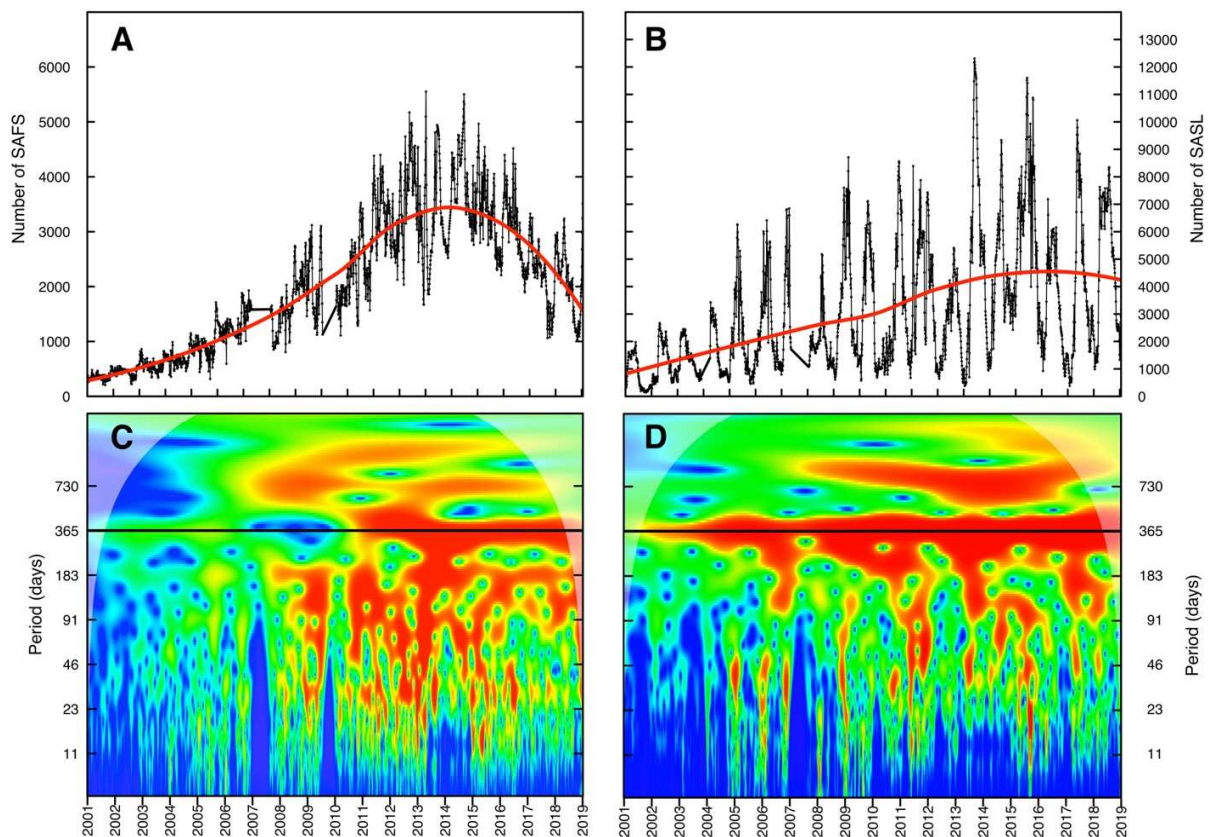

328 Throughout the abundance time series, there is always a higher abundance of SASL in  
329 comparison to SAFS, with a median ratio of 1.65 SASL : 1 SAFS. The ratio of SASL to SAFS  
330 starts at a maximum ratio of 2.84 SASL : 1 SAFS, followed by decreasing phase that hits a  
331 minimum of 1.23 SASL : 1 SAFS in October 2012. Then, a final increase phase that rises until a  
332 ratio of 2.75 SASL : 1 SAFS in December 2019.

333

334 In general, both species started with a positive increasing phase and then both declined toward a  
335 negative phase, with differing dates at each turning point. Turning points were detected as the  
336 date when a change from positive to negative phases occurred. First, SAFS changed its phase  
337 from positive to negative in November 2014. Then, 2.25 years after (in March 2017), SASL  
338 changed its phase and started to decline. Linear regressions ( $p < 0.05$ ) were adjusted to  
339 standardized data of the (negative) declining phase for each species. Slopes were significantly  
340 different from zero in both species ( $R^2 = 0.99$ ,  $p < 0.05$ ); being slope incline of SAFS ( $B_0 = -$   
341  $179.35 \pm SE 0.21$ ) steeper than SASL slope ( $B_0 = -97.33 \pm SE 0.23$ ).

342

343 The difference between first orders derivatives describes which of the species had a higher  
344 growth rate, at a given time, in comparison to the other. We used these values to organize the  
345 time series into three different periods. Sea lions had a greater growth rate in comparison to  
346 SAFS, during the first period (January 2001 - June 2007) and in the third period (March 2012 -  
347 December 2019). SAFS had a stronger growth rate in comparison to SASL during the second  
348 period (June 2007 - March 2012).  
349

350  
351 **Figure 2.** Top panel shows 3-day interpolated counts (black line) with trend of abundance (red  
352 line) for A) SAFS and B) SASL collected in Punta San Juan, Peru. Bottom panel shows wavelet  
353 spectrum with horizontal line indicating the annual signal at 365 days for C) SAFS and D) SASL  
354 abundance time series.

355

### 356 3.2 Age-class proportions

357 Median age-class proportions (Median, IQR) and mean mass (Mean  $\pm$  SD) estimated for the  
358 entire time series are reported in Table 1. Due to the non-normal distribution of datasets, we  
359 applied the Mann Whitney Wilcoxon Test ( $p < 0.05$ ) with Bonferroni p-adjustment. Significant  
360 differences were found between mean mass of all age-class proportions within species and  
361 between species ( $p < 0.05$ ), with SASL being of a significant larger size (x1.5 larger) than SAFS  
362 (Table 1). Between the adult sexes, territorial male SAFS are 2.23 larger than adult female SAFS  
363 and territorial male SASL are 3.74 times larger than adult female SASL.

364

365 Significant differences were found between weighted age-class proportions (product of mean  
366 mass and number of individuals) of each species between breeding and non-breeding seasons  
367 (Mann Whitney Wilcoxon Test,  $p < 0.05$ ), during the final period of the study (March 2012 -  
368 December 2019) (Figure 3), suggesting low intraspecific competition between age-classes at this  
369 scale.

370

371 Time series of age-class proportions with smooth loess curve and 95% CI were compared during  
372 November 2003 – December 2019 (Figure 4). Evident shifts in proportion of age-classes include  
373 i) increase in adult females (+0.2 SASL and +0.1 SAFS) between 2016 - 2018; ii) decrease in  
374 juveniles (-0.40 SASL and -0.30 SAFS) from 2015 – 2019; iii) decrease in sub adult males (-0.10  
375 SASL and -0.05 SAFS) between 2007 - 2015; iv) decrease in territorial males (-0.10 SASL)  
376 between 2008 - 2013. All the other ages class proportions are relatively stable. These trends  
377 suggest that the population decline in recent years in both species is associated to a decrease in  
378 the juvenile and, to a lesser extent, the sub-adult male age-classes at PSJ.

379

### 380 **3.3 Biomass time series**

381 Total otariid biomass time series was in the range of 83.16 – 506.72 t with a mean of  $335.26 \pm$   
382  $139.95$  t and reached its maxima in March of 2016. Throughout the time series  $82.61 \% \pm 3.75$  of  
383 total biomass is composed on average by SASL (range: 77.72 - 88.97 %), and  $17.39 \% \pm 3.75$  by  
384 SAFS (range: 11.03 – 22.28 %). This trend continues until the end of the study period, with  
385 88.63 % of otariid biomass comprised by SASL and 11.36% by SAFS in the end of 2019. SASL  
386 occupy a biomass in the range of 73.99 – 406.25 t with a mean  $272.97 \pm 108.61$  t, reaching its

387 maxima in March 2017. Whereas SAFS occupy a biomass of 9.17 – 108.41 t with a mean of  
388  $62.30 \pm 33.21$  t, reaching its maxima in November 2014 (Figure 5).

389 **Table 1.** Median proportion of age-class per species with inter-quartile range (IQR). Mean mass and standard deviation ( $\pm$  SD) in  
 390 kilograms. Sample size and source used for each age-class.

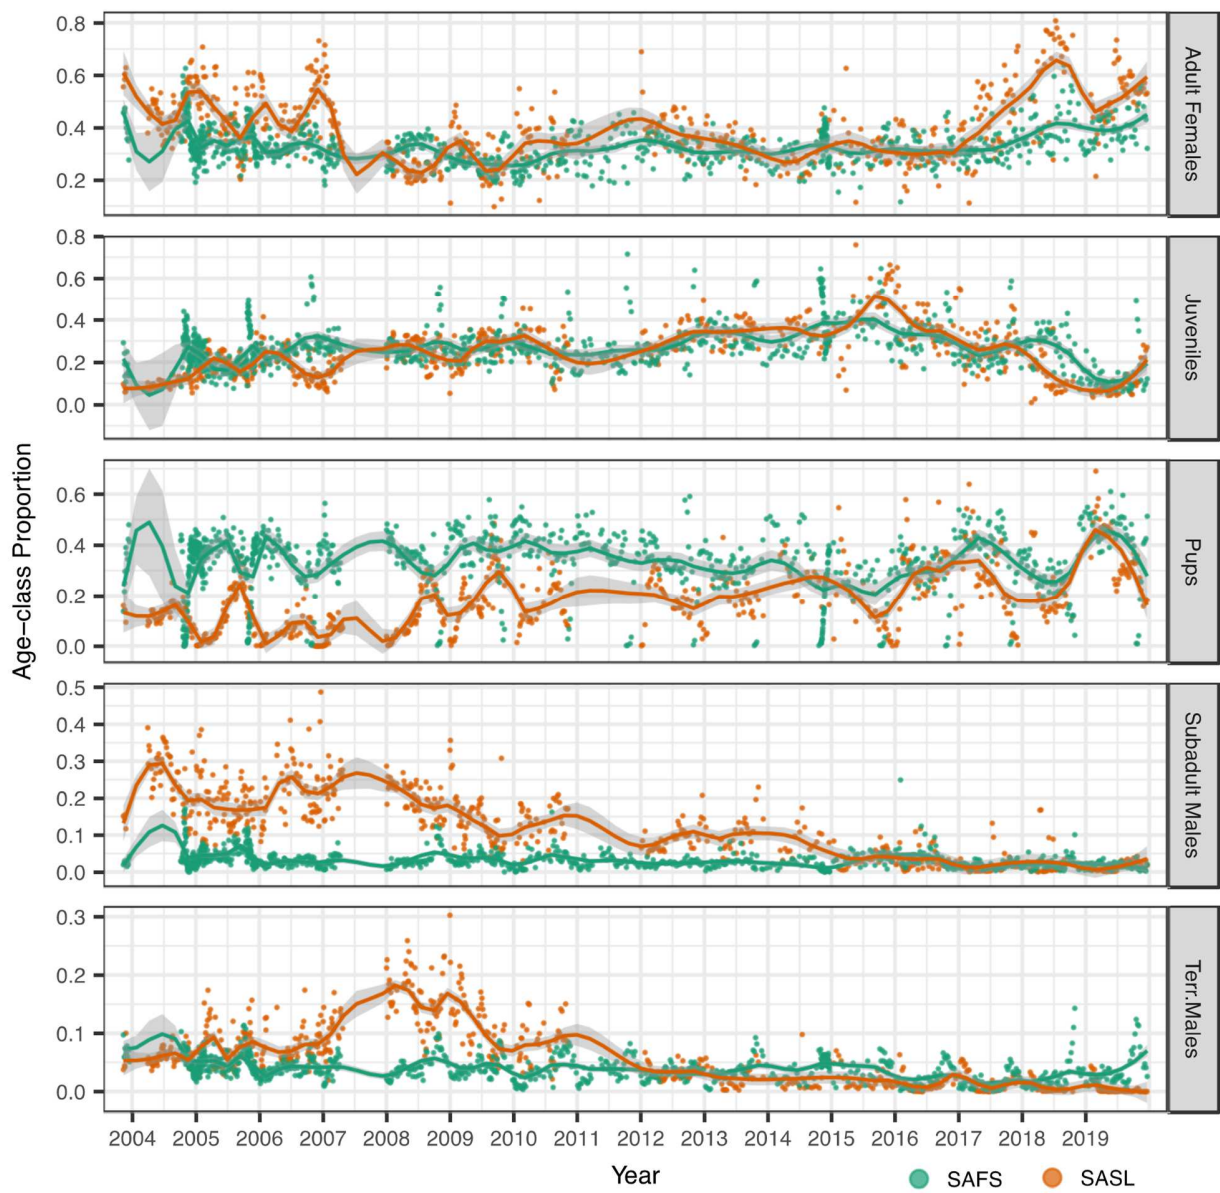

391

Species	Age-class	Proportion of age-class		Mass of age-class (kg)		
		<i>Median</i>	<i>IQR</i>	<i>Mean <math>\pm</math> SD</i>	<i>n</i>	<i>Source</i>
SASL	Pups	0.16	0.18	13.98 $\pm$ 0.62	77	This study
	Juveniles	0.23	0.17	78.88 $\pm$ 17.68	9	Hückstädt et al 2016
	Adult females	0.38	0.19	82.74 $\pm$ 11.31	23	This study
	Subadult males	0.12	0.16	173.78 $\pm$ 40.96	44	This study
	Territorial males	0.05	0.08	310	-	George-Nascimento et al 1985
SAFS	Pups	0.36	0.13	8.75 $\pm$ 0.65	171	This study
	Juveniles	0.26	0.10	24.88 $\pm$ 14.4	5606	Baker et al 1994
	Adult females	0.33	0.09	48.56 $\pm$ 8.08	91	This study
	Subadult males	0.03	0.02	66.53 $\pm$ 8.56	6	This study
	Territorial males	0.04	0.03	108.64 $\pm$ 14.20	26	This study

414

## 415 **4 DISCUSSION**

### 416 **4.1 Changes in abundance, density and population trajectories**

417 Since the effects of the Extraordinary ENSO in 1997-98 that caused otariid mortality and  
418 dispersal, it took SAFS 13 years and SASL 15 years to reach peak abundances similar to levels  
419 in 1980s and 1990s. Decomposition of time series of counts and biomass during years 2001-2019  
420 shows that both species had a growth phase, a turning point and are currently in a declining  
421 phase. Our analyses reveal that SAFS abundance began to decline ~2.25 years before SASL and  
422 at a rate 1.5 times faster than SASL. The current phase of decline in SASL was unexpected and  
423 was only detectable with an in-depth analysis of the population trajectories and associated  
424 variables. In this study we also found a decrease in the juvenile and (to a lesser extent) in  
425 subadult male age-class proportions in both SASL and SAFS that is contributing to the recent  
426 decline detected in both species (Figure 4). Decrease in juveniles and subadult males can be  
427 attributed to an increase in mortality or dispersal of these age-classes, exacerbating failure of  
428 recruitment in PSJ. Unfortunately, we do not have information to adequately address mortality or  
429 dispersal. Furthermore, in our study we did not find any evidence for intraspecific competition at  
430 population level (Table 1, Figure 3). However it is possible that intraspecific competition can be  
431 operating at another scale, such as in the overlap of resource utilization or in use of foraging  
432 grounds, that should be further explored.

433

434 The trend in biomass in this study between species shows that, on average, 83% of all otariid  
435 biomass is composed by SASL and 17% by SAFS, making SASL the current ‘dominating’  
436 species, as hypothesized. In the final phase of the time series 89% of total otariid biomass  
437 belongs to SASL, marking a large difference in the current composition between the two  
438 sympatric otariid species that inhabit the PSJ study site. Total SASL abundance is 1.23 - 2.84  
439 times larger in comparison to SAFS, with an median ratio of 1.65 throughout the entire time  
440 series. We think this can be related to the different mechanisms of congregation employed by  
441 each species, evidenced at PSJ. The aggregation of individuals on land is different when we  
442 examine raw counts of otariids at PSJ over time (Figure 2A-B). Following recolonization, raw  
443 counts show that SAFS increments with what appears to be an exponential rate at PSJ (Cárdenas-

444 Alayza, 2012) that grows accumulating individuals at PSJ. Meanwhile, SASL shows pulse-like  
445 increments with seasonal peaks of abundance that can vary widely between years. However, as  
446 SAFS abundance increments plateau and then decrease, populations pulses of SASL have been  
447 up to four times the abundance of SAFS (Figure 2A-B). This variability in the recruitment of  
448 individuals in a given breeding season has played an important role in the population growth of  
449 SASL at PSJ.

450

451 A model for male dispersal proposed by Giardino et al. (2016) developed in the Atlantic  
452 population of SASL shows that male sea lions disperse between winter haulouts and breeding  
453 sites. Haulouts can be spatially segregated from central breeding areas during the non-breeding  
454 season, and are followed by male dispersal towards breeding sites in consecutive years. Males  
455 tend to have strong site fidelity to both breeding and haul-out sites maintaining functional  
456 connectivity and gene flow throughout their range (Giardino et al., 2016). This same  
457 phenomenon contributes towards the recruitment of new individuals at breeding sites and can  
458 also be occurring in Peru, with PSJ being a reproductive site where individuals that haul-out at  
459 different sites congregate to breed. Furthermore, as evidenced from the raw counts and intra-  
460 annual dynamics (Appendix A), SASLs leave the PSJ breeding rookery decreasing their  
461 abundance during non-breeding months. In contrast, SAFS female, juveniles and pups are found  
462 year-round at PSJ to complete extended lactation periods (up to 36 months), during which  
463 females, juveniles and pups show site fidelity towards lactation sites (Majluf, 1989). Thus, high  
464 dispersal rates in SASL seem to be key for augmenting population growth in a given breeding  
465 season permitting the recruitment of more individuals for breeding. However, the decline in  
466 juvenile and subadult age-classes suggests that PSJ is not a successful site for the recruitment of  
467 these age-class in both otariid species in recent years.

468

469 Otariid breeding sites tend to show seasonal age-class proportions that reflect the roles of age-  
470 classes and sexual segregation in their polygynous mating system (Bartholomew 1970). In this  
471 study we found that PSJ breeding sites are occupied by different proportions of age-classes  
472 during breeding and non-breeding season in both species, with females, pups and juveniles being  
473 the most important age-classes throughout the year. Intra-annual dynamics show that from July

474 until December, the abundance of all SASL age-classes decrease to very low and can reach zero  
475 abundance in PSJ. In contrast to SAFS, which is present year round, and has a slight decrease in  
476 July-August (Appendix A). The wide variability in SASL in comparison to SAFS over the study  
477 period is promoted by the arrival of larger number of animals in a given season and the higher  
478 density at the breeding sites. Interestingly SAFS show a higher proportion of pups : female ratio  
479 than SASL (Figure 4), which suggests that female condition may be better in SAFS. However,  
480 this can be explained by the high site fidelity of breeding female SAFS at this site, where  
481 experienced breeders return to pup (Majluf, 1989). Whereas in SASL, it is possible that a bulk of  
482 the SASL females are young females.

483

484 In this study we found that SASL density ( $0.40 \pm 0.23$  ind / m<sup>2</sup>) at PSJ during breeding was 3-4  
485 times SAFS density ( $0.12 \pm 0.08$  ind / m<sup>2</sup>). This can be explained by the difference in the social  
486 tactics intrinsic to each species. Soto and Trites (2011) reported a lek-like mating system in  
487 SASL with the highest female : male ratio recorded for this species in Ballestas Islands in Peru,  
488 about 250km from our study site. Large abundances of females congregate to breed at what some  
489 authors identify as population “hotspots”. These high density aggregations have been explained  
490 as a means to enhance mate selection (Soto and Trites, 2011). Territorial males line up at the tide  
491 line to display themselves to reproductive females. Females benefit from male competition and  
492 avoid subadult male harassment while remaining in close proximity to foraging sites (Bradbury  
493 and Gibson, 1983, Soto and Trites, 2011). Although there are no studies on the SASL mating  
494 system at PSJ, we suppose that the social tactics described above also occurs and PSJ is an  
495 important site for SASL breeding (S. Cárdenas-Alayza, personal observation).

496

497 We know from historical records that the SAFS population ranged between 9,644 - 14,303 and  
498 SASL between 3,249 – 5,836 at the PSJ study site in 1978-79 (Figure 1). This shows that PSJ is  
499 able to support larger abundances of these species on land and in the surrounding marine  
500 environment. Interestingly, during the post 1997-98 ENSO recolonization process, SAFS  
501 gathered in lower densities than SASL. Pre ENSO density of SAFS at PSJ was reported between  
502 0.5 - 1 ind / m<sup>2</sup> (Majluf, 1989), considerably higher than average current density of  $0.12 \pm 0.08$   
503 ind / m<sup>2</sup> found in this study. In the 1980s and 1990s, 48% pup mortality was recorded in SAFS in

504 PSJ. This was caused by maladaptive aggression of females towards pups, attributed to the high  
505 density aggregations (Harcourt, 1992a, 1992b; Majluf, 1992). Furthermore, SAFS currently  
506 occupies many more beaches for breeding in PSJ in lower density, in comparison to the pre  
507 1997-98 ENSO era (Cárdenas-Alayza, 2007). Other studies have demonstrated that habitat  
508 selection for breeding sites by SAFS and SASL varies in Peru, and is driven by access to water  
509 or shade for thermoregulation (Stevens and Boness, 2003). Therefore, availability of suitable  
510 habitat features will also play a role in the occupation of breeding sites in a given area so that  
511 each species can efficiently operate mating tactics characteristic of species social system.

512

#### 513 **4.2 Contributing factors of population fluctuations in Peruvian otariids**

514 All species of otariid seals throughout the world were once subject to extensive and, in most  
515 cases, excessive hunting pressure during the eighteenth, nineteenth and twentieth centuries. By  
516 the late 1800s, however, most species had acquired total legislative protection or were subject to  
517 only regulated managed harvests (Wickens and York, 1997). Despite this protection, populations  
518 of various sea lion species have experienced very little recovery, and in some cases, are  
519 declining, and fur seal species have generally experienced rapid population recovery rates (Costa  
520 et al., 2007; Wickens and York, 1997). In Peru, we have the opposite case, a smaller fur seal  
521 population and a more abundant sea lion population. The current lack of recovery of SAFS in  
522 Peru may be explained in part by little time for SAFS population to recover from historical  
523 commercial exploitation, in synergy with recurring ENSO events and competition with fisheries  
524 and other predators (Majluf, 1991; Oliveira, 2011).

525

526 In Peru, SAFS were under more exploitation pressure due to the interest driven by the higher  
527 value of their pelts in the international fur trade market. By early 1900s, fur seal colonies in Peru  
528 were reported as small and isolated, describing this species as “close to the brink of extinction”  
529 (Murphy, 1925). The first commercial ban for otariids was legislated in Peru in 1946, prohibiting  
530 culling of adult female and pup SAFS (Majluf and Reyes, 1989). In 1950s fur seal abundance  
531 continued to be low which resulted in an extension of this ban to include all SAFS age-classes  
532 and also female SASL. Exploitation of otariids was reactivated in 1967 until early 1970s.

533 Finally, in 1976 commercial exploitation of both species was banned in Peru (Tovar and Fuentes,  
534 1984).

535

536 In mid 1950s began the development of the industrial fishery for Peruvian anchovy (*Engraulis*  
537 *ringens*) in Peru, and has turned into the largest monospecific fishery in the world capturing  
538 between 4-12 million tons of fish annually (Chavez et al., 2008). Direct links have been found  
539 between anchoveta biomass and population abundance of other top marine predators in HCS,  
540 such as seabirds, that rely almost exclusively on this marine resource for growth, reproduction  
541 and survival (Barbraud et al., 2018; Bertrand et al., 2012; Passuni et al., 2016). In synergy with  
542 ENSO conditions, overfishing can have acute effects on the survival of predator populations in  
543 HCS (Oliveira, 2011). After the effects of the 1997-98 ENSO, a mere abundance of 6,257 SAFS  
544 was recorded on the coast of Peru from a previous count of 24,481 in 1996 (Arias-Schreiber and  
545 Rivas, 1998). After some time, nationwide 2006 survey showed that the population had  
546 recovered to an abundance of 15,137 SAFS (IMARPE, 2006). However, the SAFS population  
547 recovery was also limited geographically. Of the entire current abundance, 80% resides at five  
548 sites on the entire coast of Peru (IMARPE, 2013). In comparison, 44,725 SASL were counted in  
549 Peru in 1999 after the 1997-98 ENSO, from a previous abundance of 143,713 in early 1997  
550 (Arias-Schreiber and Rivas, 1998; Oliveira, 2011). In 2006, recovery of SASL was documented  
551 with a count of 118,220 (IMARPE, 2006). In these years, SASL, breeding colonies and haulouts  
552 were already widespread along the coast compared to SAFS. For both species, authors suggest  
553 that recovery is due to the re-establishment of prey populations, the lack of strong ENSO events  
554 and migration from individuals in the colonies in northern Chile (Cárdenas-Alayza, 2012;  
555 Oliveira et al., 2012), but the fact that SASL was not reduced to such a small abundance seems  
556 fundamental to their recovery potential.

557

558 Our results show that SAFS recently declined at a rate 1.5 faster than SASL. The steeper decline  
559 in SAFS, is possibly linked to reduced recruitment in breeding adults at PSJ in recent years in  
560 combination with juvenile dispersal and mortality from this site. In our study, the sympatric  
561 otariids are exposed to the same environmental conditions, reason why the difference in this  
562 response can also be linked to intrinsic species traits that respond differently to the changes in the

563 environment. A populations risk of extinction will depend both on the deterministic (harvest,  
564 commercial exploitation, natural selection, etc.) and stochastic (environmental, genetic, etc.)  
565 processes. The latter are more pronounced at small population sizes and can accelerate extinction  
566 process started by deterministic factors (Palstra and Ruzzante, 2008). Previous studies have  
567 shown that the effective population ( $N_e$ ) is used as a tool to evaluate viable populations. High  $N_e$   
568 values retain high levels of genetic diversity and reduce probability of effects from inbreeding  
569 depression (Oliveira et al., 2006, 2012; Wright, 1990). Whereas a population with a low  $N_e$ , is  
570 susceptible to genetic drift and less apt to respond to selection (Oliveira, 2011).

571

572 After the 1997-98 ENSO, SAFS have a critical  $N_e$  value of 2,153 (Oliveira et al., 2006) while  
573 SASL  $N_e$  is 7,715 (Oliveira et al., 2012). According to Oliveira et al (2009) population  
574 reductions after the 1997-98 ENSO, may have caused a significant genetic bottleneck in the  
575 Pacific population of SAFS and SASL, with loss of genetic diversity and presumably some loss  
576 of evolutionary potential for the species (Oliveira et al., 2009; 2012). Furthermore, the rate of  
577 loss of genetic diversity via genetic drift is greater in populations where  $N_e$  is small and  
578 migration is limited, as is the case for SAFS. This can be evidenced in the information gathered  
579 through Peru's nationwide surveys, where >90% of SAFS breeding population is mostly  
580 restricted to latitude 15 -17° South, with PSJ supporting at least 40% of entire Peru SAFS  
581 population. Meanwhile, SASL population is distributed continuously along the coast, with  
582 important breeding sites in several latitudes (6, 13-14, 15 and 17° South) (IMARPE, 2018, 2017,  
583 2016). Wider distribution of breeding sites with high density aggregations of SASL, suggest that  
584 migration and dispersal rates in SASL are higher than SAFS, resulting in higher connectivity.  
585 Therefore, even if there was genetic loss due to a bottleneck from a strong ENSO event, SASL  
586 has mechanisms to counterbalance loss of genetic diversity with temporal gene flow through  
587 migration. The difference in gene flow between these two species in HCS can be a key factor  
588 explaining the limited response to achieve population growth under scenarios of environmental  
589 change in SAFS in comparison to SASL suggested in this study, and should be further studied.

590

591 **4.3 Natural history traits that influence interspecific competition in otariids**

592 Body size of SASL is overall 1.5 larger in all age-classes compared to SAFS. In this study,  
593 although we hypothesize that a larger body size (SASL) could serve as advantageous to consume  
594 larger/ more prey, the decline in population abundance of both SAFS and SASL suggests that a  
595 resource limitation is affecting trajectories of both species. Between the sexes, territorial male  
596 SAFS are 2.23 larger than adult females and SASL males are 3.74 times larger than adult SASL  
597 females. Although at population level we did not find evidence for segregation between age-  
598 classes and sex, mechanism to avoid competition may be operating at a different scale. To  
599 elucidate differences and how these species are exploiting the environment, further studies need  
600 to be conducted to test intra and interspecific trophic niche segregation to understand how these  
601 sympatric otariid species exploit the HCS.

602

603 In our study we compared otariid biomass as a possible outcome of interspecific competition in  
604 PSJ and found that 83 % of total average biomass is composed by SASL throughout our time  
605 series. This can be explained by a the difference of 1.6 - 3.3 in mass between SASL and SAFS;  
606 in combination with a high density mating system in SASL versus lower density aggregations in  
607 SAFS. Researchers have examined potential competition between sympatric fur seal and sea  
608 lions at other locations and have found in some cases that trophic segregation is a mechanism to  
609 explain differing foraging strategies and contrasting population trends (Franco-Trecu et al., 2014;  
610 Pablo-Rodríguez et al., 2016; Páez-Rosas et al., 2012). Some authors suggest that difference in  
611 divergent trends is explained thru epipelagic and benthic foraging, being the latter characteristic  
612 of sea lions that have larger body size and diving capacity (Arnould and Costa, 2006). Other  
613 studies have also demonstrated that different age-classes within the same sea lion population  
614 have specialized benthic and epipelagic foraging modes (Jeglinski et al., 2013; Villegas-  
615 Amtmann et al., 2013). Therefore, otariid foraging ecology in PSJ needs to be evaluated at  
616 interspecific and intraspecific level to understand how the different groups are exploiting the  
617 local environment.

618

619 In the coast off PSJ, the continental shelf is extremely narrow limiting the access to benthic  
620 habitat. Furthermore, previous studies in Chile have demonstrated that SASL are epipelagic  
621 foragers with mean dives of  $29.0 \pm 34.8\text{m}$ , when they are in an upwelling environment

622 (Hückstädt et al., 2014, 2016). Therefore, we expect that competition for similar prey items may  
623 be taking place within the upper limit of the oxygen minimum zone off the Peru coast, which is  
624 usually located ~50 m in depth (Bertrand et al., 2010) making the foraging habitat of pelagic  
625 prey readily available for both otariid species diving capacity, independent of differences in body  
626 size.

627

628 It is well documented that the HCS in Peru holds a world-leading monospecific forage fishery in  
629 terms of landings of Peruvian anchovy, sustaining >5 million tons per year on average since  
630 1960s (Bakun and Weeks, 2008; Chavez et al., 2008). In Peruvian otariids, the number of pups  
631 born, mean birth dates and anchovy biomass were found to have direct relationships in SASL  
632 and SAFS reproductive success, demonstrating that anchovy is a key resource in fulfilling the  
633 energetic demands of both species (Cárdenas-Alayza, 2012; Soto et al., 2004). Other studies  
634 have evaluated diet composition between these sympatric otariids in the decades of 1980s and  
635 late 1990s in south Peru, but conclusions for resource partitioning are not clear. Vásquez (1995)  
636 reported that otariid diets were both based on fish and cephalopods; with Peruvian anchovy  
637 (*Engraulis ringens*) and Jack Mackerel (*Trachurus murphyi*) as the main consumed species.  
638 Afterwards, Arias-Schreiber (2000) found that Peruvian anchovy, squids and a crustacean, the  
639 Red squat lobster (*Pleuroncodes monodon*), were ranked as important prey items shared by the  
640 sympatric species. Based on this, we understand that anchovy is an important prey shared by  
641 both otariids during these study periods, but mechanisms for trophic segregation are not clearly  
642 explained. Furthermore, prey availability may have changed in the last 20 years. Therefore,  
643 resource partitioning research needs to be updated and further explored in these sympatric  
644 species to disentangle current resource utilization in relation to population trajectories.

645

#### 646 **4.4 Current and future trends**

647 In the final 5 years of our time series, both sympatric otariid populations were found to be in a  
648 state of decline. SAFS were the first to decline in 2014, which coincides with a decrease in the  
649 anchovy biomass estimated for the coast of Peru during this period. Anchovy biomass dropped  
650 from 11,201 tons in 2013 to 3,799 tons in 2014 (Zavala et al., 2019). In 2014 anchovy landings  
651 summed 1,302 tons, leaving an available biomass of 2,497 tons for all predators and other

652 fisheries to consume, which may have posed limitations for growth and maintenance of predator  
653 populations. Warmer oceanographic conditions in HCS persisted and coincided with a reduced  
654 anchovy biomass from 2014 to 2017 (Zavala et al., 2019). Changes in oceanographic conditions  
655 can shrink and expand available habitat for prey items forcing new competition scenarios  
656 between coexisting species. Thus, under a scenario of reduced anchovy biomass we consider it is  
657 possible that prey availability is limiting population sizes at PSJ and can be responsible for the  
658 declines observed in the juvenile and subadult age-class for both SAFS and SASL; as younger  
659 individuals do not possess full diving capabilities.

660

661 Predictions for the future of HCS include scenarios with shoaling of the oxycline (Brochier et al.,  
662 2013), compressing the pelagic habitat that sustains the abundant biomass of small pelagic fish  
663 currently in the system (Bertrand et al., 2011). If this occurs, it will increase competition between  
664 all the predators that depend on pelagic resources, unless they adapt foraging strategies under  
665 new conditions. Under this hypothetical predicted scenario and our findings, we suspect SASL  
666 will be the more resilient of the two sympatric otariid species that will thrive in HCS, given its  
667 population recovery in the past 20 years. Therefore, to propose adequate management for the  
668 future of these species, it is important to better understand current underlying foraging strategies  
669 used by otariids of HCS and determine if trophic competition rules over space and time between  
670 species. These studies are key to tease apart the underlying mechanisms behind the current  
671 population trajectories revealed by the present study.

672

## 673 **5 ACKNOWLEDGEMENTS**

674 This study is part of the doctoral dissertation of the first author, developed at the Escuela  
675 Doctoral Franco Peruana en Ciencias de la Vida, Universidad Peruana Cayetano Heredia and  
676 École Doctorale GAIA Biodiversité, Agriculture, Environnement, Terre, Eau, Université de  
677 Montpellier, France. Data collection in Punta San Juan was possible thanks to the  
678 interinstitutional collaboration agreements between Universidad Peruana Cayetano Heredia,  
679 SERNANP – MINAM and AgroRural - MINAGRI. We would like to thank SERNANP for  
680 access to Punta San Juan reserve and AgroRural for the use of facilities in the field. We would  
681 also like to acknowledge support from the consortium of North American zoos (Chicago

682 Zoological Society, Saint Louis Zoo, Kansas City Zoo and Woodland Park Zoo) that fund the  
683 field operations of the Punta San Juan Program which are essential to collect the long term  
684 dataset analyzed in this investigation. Most importantly, we thank all the volunteers, interns and  
685 personnel of the Punta San Juan Program that have helped collect this valuable information over  
686 the years.

942

943

#### 944 **Appendix A. Supplementary data.**

945 Intra-annual dynamics of South American fur seals and South American sea lions by age-class.

946

#### 947 **Multimedia Component 1.**

948 Multi-panel plot of South American fur seals counts by age-class according to day of year  
949 collected at the main breeding site S3 in Punta San Juan, Peru. Classes include: Adult  
950 Females, Juveniles, Pups, Subadult Males and Territorial Males. Total is the sum of all the  
951 age-classes. Blue line is a fitted loess model to depict the trend in abundance throughout the  
952 year. Data points include all study years available for site.

953

954 **Multimedia Component 2.**

955 Multi-panel plot of South American sea lions counts by age-class according to day of year  
956 collected at the main breeding site N7 in Punta San Juan, Peru. Classes include: Adult  
957 Females, Juveniles, Pups, Subadult Males and Territorial Males. Total is the sum of all the  
958 age-classes. Blue line is a fitted loess model to depict the trend in abundance throughout the  
959 year. Data points include all study years available for site.

Information collected for 19 years in Punta San Juan, Peru. An important sympatric breeding site for pinnipeds of the Humboldt Current System.

**STUDY SPECIES**

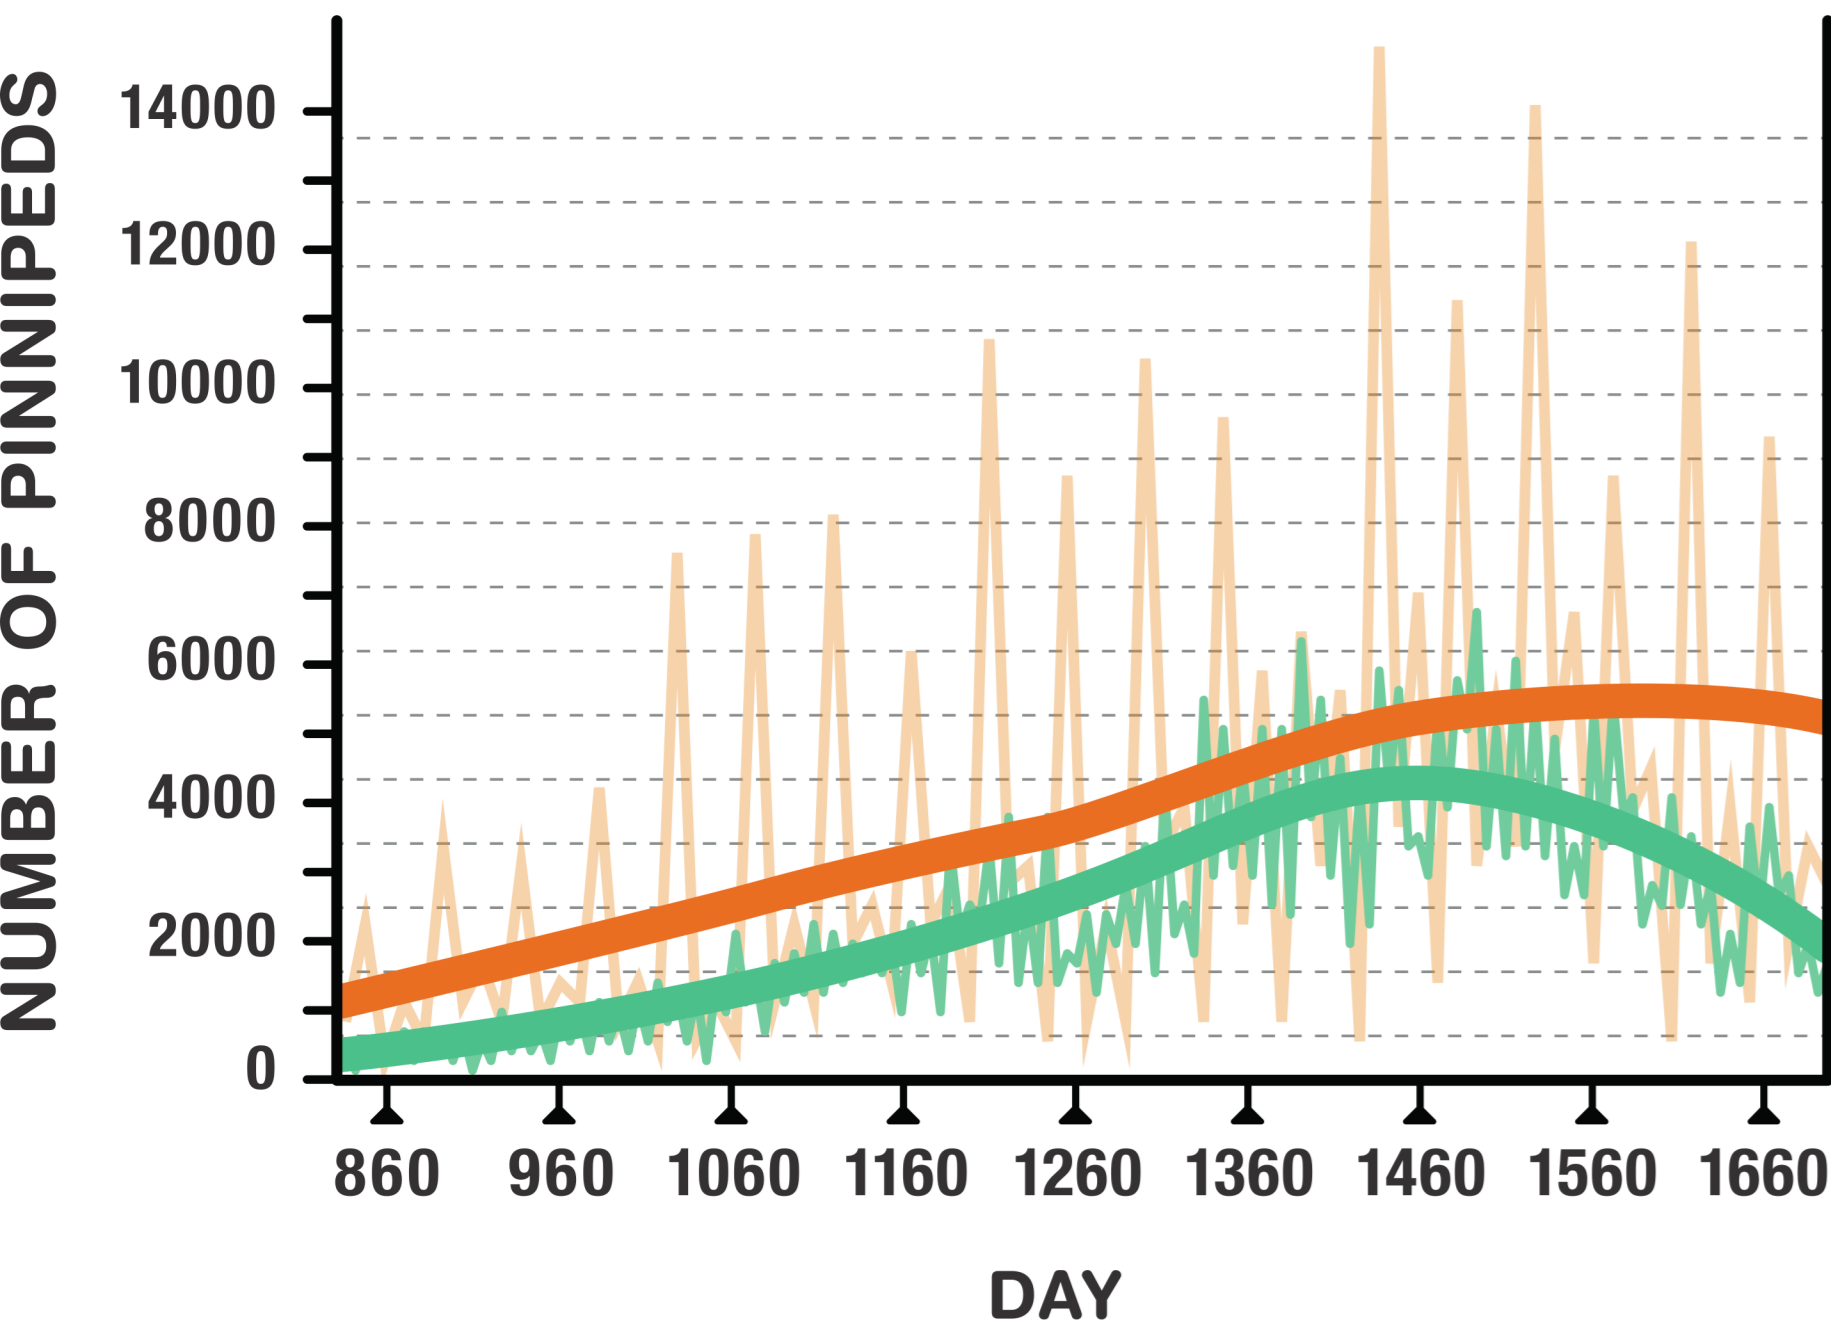

**South American sea lions**

**South American fur seals**

**ABUNDANCE TIME SERIES (2001-2019)**

**MASS FOR EACH AGE-CLASS**

**BIOMASS TIME SERIES**

**Resource limitation may influence recent trends in Peruvian otariids**
