#### Abstract :

Spatial conservation prioritization (SCP) is a planning framework used to identify new conservation areas on the basis of the spatial distribution of species, ecosystems, and their services to human societies. The ongoing accumulation of intraspecific genetic data on a variety of species offers a way to gain knowledge of intraspecific genetic diversity and to estimate several population characteristics useful in conservation, such as dispersal and population size. Here, we review how intraspecific genetic data have been integrated into SCP and highlight their potential for identifying conservation area networks that represent intraspecific genetic diversity comprehensively and that ensure the long-term persistence of biodiversity in the face of global change.

#### Highlights

► Conservation area networks on land and sea need to be expanded to meet the objectives of the post-2020 global biodiversity framework. ► Spatial conservation prioritization (SCP) is a rigorous framework to identify suitable areas for protection on the basis of scientific data. ► Integrating intraspecific genetic data in SCP can help identify networks of conservation areas that are more representative of biological diversity and likely better at ensuring its long-term persistence.

**Keywords :** adaptive genetic diversity ; biodiversity features ; evolutionarily significant units ; reserve design ; systematic conservation planning

#### 44 Main

#### 45 The benefits and challenges of intraspecific genetic data for spatial conservation

#### 46 prioritization

Facing worldwide declines in biodiversity and nature's contributions to people [1], the post-2020 global biodiversity framework under discussion by the UN will prescribe to create "ecologically representative and well-connected" networks of conservation areas (CAs) that cover 30% of marine, aquatic and terrestrial habitats, and to ensure that 90% of within species genetic diversity is maintained by 2030 (see www.cbd.int/conferences/post2020). To achieve these goals, spatial conservation prioritization (SCP) is an effective framework to identify new CAs on the basis of the spatial distribution of conservation costs and biodiversity features (see Glossary) such as species and ecosystems [2].

54 Over time, SCP has evolved to integrate increasingly complex aspects of biodiversity, such as connectivity, 55 ecosystem services and functional diversity [3–5]. Recently, attempts have been made to use intraspecific 56 genetic data to gain knowledge on several aspects of species' biology that are critical for their conservation 57 (see also Online Supplemental Information Table S1). In particular, genetic data can provide information 58 on intraspecific genetic diversity, dispersal and population size [6,7]. The published studies listed in Table 59 **S1** show that such information can increase the **comprehensiveness** of CA networks and the long-term 60 persistence of biodiversity. However, the successful integration of intraspecific genetic data with other types of data in SCP presents challenges. Here, we briefly review the available techniques to estimate 61 62 intraspecific genetic diversity, dispersal and population size from intraspecific genetic data and we discuss 63 how to best integrate them in SCP.

#### 64 Obtaining unbiased information from intraspecific genetic data

#### 65 Intraspecific genetic diversity

66 Species are not static in time and show phenotypic variation throughout their range. This intraspecific 67 diversity, which arises through the interplay of environmental and genetic variation, has consequences for 68 population viability, community and ecosystem functioning, and nature's contributions to people [8,9]. 69 Intraspecific variation is an important asset that can allow species to persist in the face of rapid 70 environmental change, such as those expected from the outcomes of global climate change [10]. There is 71 evidence that intraspecific genetic diversity has declined in many wild species [11,12]; therefore, the post-72 2020 biodiversity framework will commit to protecting intraspecific genetic diversity and CAs can be a 73 valuable tool to reach this objective [13].

74 Intraspecific genetic diversity can be partitioned into within-population diversity and between-population 75 diversity, analogous to partitioning species diversity into alpha and beta components [14]. Within-76 population genetic diversity can be measured using metrics such as allelic richness and observed and 77 expected heterozygosity, while between-population genetic diversity can be represented by metrics of 78 genetic differentiation [15]. Genetic differentiation can be used to identify conservation units below the 79 species level, such as management units (MUs) and evolutionarily significant units (ESUs) [16]. The 80 maintenance of genetic differentiation between MUs implies significant demographic isolation or selection 81 against immigrants, which justifies considering them as distinct conservation units [16]. Conversely, 82 genetically homogenous sets of individuals cannot be considered as MUs given that the level of migration 83 that is sufficient for genetic homogeneity might not be sufficiently high to ensure demographic 84 connectivity [17,18].

ESUs are populations or groups of populations that have evolved independently and can be identified by
reconstructing phylogenetic trees within species [16,19]. ESUs are important conservation units because a

87 comprehensive view of biodiversity includes the full set of nested clades representing phylogenetic 88 relationships among organisms [20]. In addition, regions with maximum phylogenetic diversity for a given 89 taxon will also have the greatest trait diversity and thus potential to respond evolutionarily to future 90 environmental change [21]. Finally, focusing on ESUs instead of species can help conserve biodiversity 91 when taxonomy is uncertain [22]. Although the identification of ESUs has frequently relied on finding 92 monophyletic clades [19], the general agreement is that ESUs should not be designated solely on the basis 93 of genetic distinctiveness: ecological exchangeability and existence of genetic adaptations are among the 94 proposed criteria to define ESUs [16,23,24]. Furthermore, the steps and choice of methods involved in 95 reconstructing phylogenies can influence the inferred relationships among population units [25,26].

96 A further distinction can be made between neutral genetic diversity and adaptive genetic diversity 97 according to the effects of genetic variation on individual and population fitness [27]. However, the effect 98 of different alleles on the fitness of individuals and the viability of populations is seldom known, especially 99 for non-model organisms. Genotype-phenotype association studies aim to identify genes responsible for 100 phenotypic variation through correlative tests between variation in phenotypic traits and genetic variation 101 [28]. Such genes can be considered important for the viability of populations when the phenotypic traits 102 studied are of key importance for the persistence of populations and the identified genes have sufficiently 103 large phenotypic effects for their variation to significantly affect phenotypic variation [29]. A second set of 104 methods (outlier tests and environmental association analyses) investigate the signatures of selection to 105 detect candidate loci underlying local adaptation [30,31]. However, it is always difficult to distinguish the 106 signatures of positive selection from those of genetic drift [30] and, even when adaptive loci have been 107 identified with high confidence, the effects of their genetic diversity on population persistence usually 108 remain unknown [29]. Faced with these challenges, it is often difficult to partition neutral from adaptive 109 genetic diversity. One possibility is using genome-wide genetic variation as a proxy for the viability of 110 populations [32]. However, for some cases where genetic variation in phenotypic traits has been

quantified, neutral genetic variation has proven to be a poor predictor of adaptive genetic variance [33].
Furthermore, genomic techniques allow typing thousands of loci and if all these loci were included as
biodiversity features, they could lead to computationally prohibitive problems and redundant information.
As large genomic data sets accumulate [34], there is a need to consider how measures of intraspecific
genetic diversity can be used in SCP.

116 Dispersal

117 The post-2020 global framework emphasizes that biodiversity should be protected through "well-118 connected systems" of CAs. The functioning of systems of CAs as well-connected networks depends 119 critically on the dispersal of organisms, which facilitates recolonization after catastrophic disturbances 120 (demographic rescue) and allows the spread of adaptive variants that increase the viability of local 121 populations facing environmental change (genetic rescue). In some species, dispersal can be studied using 122 telemetry methods, but these techniques are not practical for many animal and plant species that disperse 123 during life stages (such as larvae or seeds) when they are too small to be equipped with emitters. In these 124 cases, genetic techniques can be a useful alternative to estimate dispersal at the temporal scale of a few 125 generations in the past (Box 1). Four types of methods have been identified to estimate dispersal from 126 genetic data: assignment tests [35], parentage analysis [35–37], analysis of the pattern of isolation-by-127 distance [37] and clinal analysis [38]. The results are estimates of dispersal probabilities between sites 128 (summarized in a dispersal matrix) and dispersal distances (summarized in a dispersal kernel). Each of 129 these methods has strengths and weaknesses (reviewed in [7,35]): for example, the accuracy of assignment 130 tests depends on the degree of genetic differentiation between populations, while parentage and clinal 131 analyses require intensive sampling or sequencing efforts [35] and cannot realistically be applied to a large number of species occupying an area being considered for SCP. However, gaining direct dispersal data for a 132 133 small number of representative taxa could be useful to complement other, more feasible genetic 134 approaches, such as the analysis of isolation by distance [37].

#### 135 Census and effective population size

136 Various statistical frameworks are available to estimate census population size N<sub>c</sub> from samples of 137 individuals from natural populations typed with molecular markers [39]. These methods offer a valuable 138 alternative to direct observation for obtaining estimates of population density in species that are difficult to observe and count, such as aquatic animals. For example, close-kin mark-recapture is an extension of 139 traditional mark-recapture approaches where each juvenile carries the "marks" of its parents within its 140 141 DNA [40]; using this method with a panel of 8,961 SNPs, Hillary et al. [41] estimated that  $N_c$  in the white 142 shark Carcharodon carcharias population in eastern Australia and New Zealand ranges between 2,500-143 6,750 individuals. Intraspecific genetic data are also useful to estimate effective population size N<sub>e</sub>, which 144 is related to the risk of inbreeding depression and loss of genetic diversity [42], through several statistical 145 frameworks applicable to a variety of life-histories [43]. Although uncertainty increases when the real  $N_e$  is 146 large, with appropriate sampling designs and sufficient numbers of genetic markers, genetic data can 147 provide precise and unbiased estimates of  $N_c$  and  $N_{e_r}$  in some cases using the same dataset [44]. 148 Temporally repeated sampling can provide estimates of population trends in time and thus help identify 149 declining populations [45].

#### 150 Integrating information obtained from intraspecific genetic data in spatial

#### 151 conservation prioritization

SCP can be treated as a mathematical problem using equations linking the spatial distribution of biodiversity features and conservation costs [46] (**Box 2**). While there are different formulations of SCP problems [46], almost all of them involve four parameters: the representation level  $r_{ij}$  of biodiversity feature *j* in site *i*, the cost  $c_i$  of protecting site *i*, the spatial target  $T_j$  for biodiversity feature *j*, and the adjacency cost  $cv_{ih}$  between site *i* and *h*. The general principle to integrating the estimates from intraspecific genetic data is to link them explicitly to the parameters of SCP (**Figure 1**).

#### 158 Intraspecific genetic diversity

159 There are various ways to integrate information on intraspecific genetic diversity into SCP. The simplest 160 approach is to use alleles as biodiversity features instead of (or in combination with) species ("AL" method 161 in Table 1), but it can be difficult to decide which and how many genetic markers and alleles to consider as 162 biodiversity features. Estimates of within-site diversity, such as allelic richness and heterozygosity, can be 163 used as biodiversity features ("GM"); however, defining a target of representation  $T_i$  for them is not 164 meaningful since  $T_i$  considers the total sum of a biodiversity feature across the planning area and such 165 genetic metrics are not additive across space. These metrics could be better integrated as cost layers, for 166 example by setting costs proportional to the inverse of allelic richness to select sites with high local genetic 167 diversity ("CS" method). Another option is to use site-specific metrics to rank sites according to the metric 168 of interest (e.g. sites with low and high allelic richness) and split the taxon (species or conservation unit) 169 occurrence layer into several distinct layers with specific representation targets ("ST" method).

Conservation units (MUs and ESUs), when present, can also be used directly as biodiversity features ("CU" method). As an alternative to using ESUs, the branches of the phylogenetic tree can be used directly as biodiversity features to assign higher priorities to older genetic lineages [22,47]. This approach may be useful because conserving lineages separated by longer branches results in protecting larger amounts of genetic diversity, compared to conserving more closely related lineages. In addition, using branches ensures cost-effective protection as deeper branches representing shared evolutionary histories are only accounted for once in the prioritization [48].

Some species do not have a discrete spatial genetic structure that permits researchers to unambiguously identify conservation units. A solution to this problem is to use continuous measures of genetic distance [49] in the 'environmental diversity' formulation of the SCP problem ("ED" method), used to identify a set of conservation priority sites on the basis of continuous intraspecific variation (genetic or environmental [50]).

182 Importantly, as genetic sampling is usually sparse, there will not be enough observations to measure the 183 spatial occurrence  $r_{ii}$  of alleles, conservation units or genetic metrics nor to measure costs  $c_i$  in all sites. This 184 requires a spatialization step to go from sampled points to values for all sites in the regular grid (planning 185 units) used in SCP. This can be done using several methods relying on sampled genetic data only (e.g. 186 inverse distance weighting) or making use of environmental variables (e.g. ecological niche models). 187 Supplementary Table 1 indicates the methods used for each published paper that incorporates genetic 188 data in SCP. There is currently no comparison of the various methods to infer genetic data to cover 189 unsampled sites (see **Outstanding questions**).

190 Dispersal

191 Several methods are available to constrain the sites chosen for protection to be spatially contiguous 192 [46,51,52], such as introducing a boundary cost  $cv_{ih}$  for not protecting pairs of bordering sites (**Box 2**). This 193 formulation can easily accommodate the information of dispersal contained in a dispersal matrix, whose 194 elements  $d_{ij}$  give the probabilities of dispersal from site j to site i. Whether it is estimated from genetic data 195 or obtained through other methods, the dispersal matrix can be used to define the cv<sub>ih</sub> parameter in the 196 SCP problem, which becomes a connectivity penalty cost paid when site i is chosen for protection and site h197 is not [53]. Depending on the goals of SCP, researchers can choose the extent to which connectivity should 198 be prioritized by changing parameter b, which becomes the connectivity strength modifier (Equation 2 in 199 Box 2)[53]. In other formulations of the SCP problem, the dispersal matrix can be used to maximize metrics 200 of metapopulation performance, such as the expected time to extinction [54,55]. Alternatively, dispersal 201 distances can be used to set the maximal size of CAs and distances between different CAs in a network to 202 ensure that propagules and juveniles generated in one CA can disperse to and recruit in nearby CAs [56,57].

The dispersal matrix can also be used to define site-specific metrics measuring the importance of each site
 for population persistence using graph theory [58] or matrix analysis [55]. When used as biodiversity

features [58] or costs [59], such site-specific metrics lead to the selection of sites that are well-connected,
and this connectivity may enhance persistence within the CA network [58].

207 Population size

208 Estimates of  $N_c$  and  $N_e$  are useful to refine the targets  $T_j$ 's of species representation that constrain the 209 solution of the SCP problem (equation 2 in Box 2)[60]. These targets define the minimum proportions of 210 the geographical ranges of species that need to be included in the sets of CAs to consider those species 211 adequately covered. Species with smaller geographical ranges are usually given higher proportional targets 212 of representation because they might face a higher risk of extinction than species with larger ranges [61]. 213 Despite being easy to implement, this approach is an approximation for the complexity of demographic, 214 genetic and ecological factors affecting the long-term persistence of species. Estimates of  $N_c$  and  $N_e$  could 215 help set more appropriate targets, for example by increasing  $T_i$  for species that have low numbers of 216 individuals even if their geographical range is large or for species showing a negative temporal trend in 217 abundance. The information provided by population abundance complements that of occurrence in setting 218 conservation priorities [62] and many species are showing signs of declining abundance despite keeping 219 stable geographical ranges [63]. The approach used by the IUCN to classify species into threat categories is 220 also based on criteria of geographical ranges and population abundance [64].

When estimates of  $N_c$  and  $N_e$  are available per site, they can be used to define SCP problems in terms of abundance: the representation levels  $(r_{ij})$  are the site-specific population numbers and the target  $T_j$  is the total species abundance required for long-term persistence, which can be found using population viability analysis or set following the general 50/500 rule [65–67]. This approach requires a comprehensive sampling across the range of the species, or a method to spatialize the estimates of  $N_c$  and  $N_e$ . While there are several abundance-based species distribution models that predict  $N_c$  [68], similar approaches for  $N_e$  have yet to be developed.

#### 228 Building adaptive conservation area networks

A primary goal of well-connected and genetically representative CA networks is to support the persistence 229 230 of species in the face of anthropogenic disturbance, such as land use and climate change [69]. When loci of 231 large effect on fitness can be identified, there are two alternative conservation strategies that can be 232 adopted to account for future adaptation. First, when the direction of environmental change can be 233 predicted and the relationship between alleles and environmental variables is known, a decision can be 234 made to conserve the alleles that confer stronger adaptation to future environmental conditions, or the 235 sites that show the smallest genetic offset with future predicted conditions [70]. However, focusing on the 236 winners of environmental change relies on many strong assumptions, among which that the populations 237 are optimally adapted to current environmental conditions and that the relationships between alleles and 238 environmental variables are correctly characterized. In addition, when the direction of environmental 239 change is unclear, it is even more difficult to predict biological responses accurately.

A safer strategy is to conserve a portfolio of alleles at adaptive loci (I.e. adaptive genetic diversity) as opposed to conserving only some alleles, as this confers higher adaptation capacity when future environmental conditions are uncertain [71] and buffers the risk of incorrectly characterized geneenvironment associations. Depending on the genetic structure of the species, intraspecific genetic diversity can be conserved either by prioritizing sites with the highest within-site diversity (alpha diversity) or by protecting sets of sites with complementary genetic variants to maximize adaptation capacity at the landscape scale (beta diversity; **Box 3**).

#### 247 Concluding remarks: getting the best (out of) genetic data

Despite the potential for improving CA planning, there are still numerous challenges that should be tackled
 by future research (see **Outstanding questions**). First, information from intraspecific genetic data is
 affected by various types of uncertainty [72]. Some estimated variables, such as dispersal distance and

population size, can have wide confidence intervals [37,41] and the identity of conservation units and
adaptive genetic markers often depends on the methods used [24,30]. There is also limited knowledge
about the real effects of intraspecific genetic diversity on the adaptive potential of populations [73]. An
important area for future research is to evaluate the impact of these types of uncertainties on the selection
of CAs [74] and develop standardized, efficient workflows to integrate the uncertainty of inputs into multispecies SCP [72].

257 Secondly, characterizing intraspecific genetic diversity requires multiple samples distributed throughout the 258 entire geographic range of species, and possibly replicated in time to estimate population abundance 259 trends. To estimate dispersal and population size, sampling must be carefully planned [35,43]. Multi-260 species genetic studies are becoming more common [75,76] and efforts are made to bring together genetic 261 data sets for multiple species in free databases [34]. However, intraspecific genetic data are still lacking for 262 many species and attempts to replace them with surrogate variables (e.g. environmental variables) have 263 yielded mixed results [77–79]. Obtaining spatially and temporally replicated genetic samples for multiple 264 species, in line with local conservation priorities and involving all stakeholders [80], remains a main goal for 265 future research.

266 The scientific community has set ambitious goals to obtain genomic information for wild species: for 267 example, the Earth Biogenome Project aims to sequence all known eukaryotic species in a ten-year 268 timeframe [81]. The availability of genome sequences will undoubtedly help develop genetic markers for 269 wild species, but it will be necessary to understand how to best use the knowledge obtained from 270 reference genomes [82], for example the identification of deleterious mutations and the quantification of 271 mutation load [83], to plan networks of CAs. When genomic data are used to identify putatively adaptive 272 genetic markers, SCP solutions might be similar [85] or substantially different [74,84] to those found using 273 putatively neutral loci or traditional markers such as microsatellites.

274 Similarly, conserving intraspecific genetic diversity, dispersal and population size might require specific sets 275 of sites that increase conservation costs relative to the surface area needed to conserve species, possibly 276 making it more difficult to reach other conservation objectives. This is likely to happen each time new 277 objectives and constraints are added to the conservation problem. For example, the sites needed to 278 maintain ecosystem services and functional diversity are often different from those needed to conserve 279 species [86,87]. These conflicts in CA siting are eased when the connections between seemingly different 280 objectives are recognized: for example, ensuring that marine reserves ensure population persistence within 281 their borders (biodiversity conservation objective) and fishery supply beyond their borders (ecosystem 282 service objective) can be reconciled by siting them according to the dispersal capacity of the targeted 283 species [88]. This also shows that information obtained from intraspecific genetic data has an added benefit 284 [89] and may justify the extra money and time required to obtain them.

Systematic approaches to biodiversity conservation will be increasingly needed in the near future to reach the targets of the post-2020 global biodiversity framework. Intraspecific genetic data are a wealthy source of information not only for characterizing intraspecific genetic diversity, but also for estimating important demographic parameters such as dispersal and population size. In addition to the framework briefly illustrated here, there might be other ways, which will be important to assess, to expand SCP towards these data. Early examples show that information from intraspecific genetic data is likely to improve the planning of CAs to reach multiple ecological objectives.

#### INTRASPECIFIC GENETIC DATA FROM SAMPLED SITES

- ESTIMATION
- INTRASPECIFIC GENETIC DIVERSITY
- DISPERSAL
- POPULATION SIZE

# 304 Table 1. Methods to integrate information from intraspecific genetic data in spatial conservation

305 prioritization.

METHOD	DESCRIPTION	EXAMPLES
ALLELES (AL)	Alleles are the biodiversity features. Allele presence or frequencies are mapped on the landscape and spatial layers are used as inputs in the prioritization.	[75,90–94]
CONSERVATION UNITS (CU)	Conservation units (management units, evolutionarily significant units or the branches of the phylogenetic tree) are treated as biodiversity features. As intraspecific genetic data are usually spatially sparse, the spatial distribution of individual conservation units is usually not known from observations, but can be predicted using spatial interpolation techniques or <b>ecological niche models</b> . In this latter case, each conservation unit is treated as a distinct entity in a model using environmental variables as predictors of its occurrence, with the possibility to include future environmental projections to forecast the response of each conservation unit under different climate change scenarios.	[22,47,84,95–
GENETIC METRICS (GM)	Genetic metrics, calculated for each species or conservation unit in each site, are the biodiversity features. Values in unsampled sites are predicted using spatialization techniques. A conceptual and practical difficulty with this method is the need to set representation targets for genetic metrics.	[74,93,98]
SPLIT TAXA (ST)	Taxa (species or conservation units) are the biodiversity features. Each taxon is represented by several spatial layers grouping sites sharing similar genetic characteristics. For example, distinct layers are used to represent sites with low, medium and high allelic richness or areas of low, medium and high genetic differentiation. Each layer has a spatial representation target. A limitation of this approach is that the number of distinct spatial layers and the limits among them are usually arbitrary.	[84,85,99–102]
COSTS (CS)	Costs are calculated as a function of site-specific or between-site genetic metrics. For example, sites with lower allelic richness are given higher protection costs to favor the	[99]

	selection of sites with higher genetic diversity. Pairwise genetic metrics can be integrated through boundary costs <i>cv<sub>ih</sub></i> : pairs of sites with lower genetic differentiation are given lower pairwise costs to favor the selection of genetically connected sets of sites. One drawback of this approach is the need to combine information that may be incommensurable, e.g. genetic-based and monetary costs, or when costs are used to define layers of unsuitable habitats.	
ENVIRONMENTAL DIVERSITY (ED)	The ED formulation finds the subset of sites that contain the most representative set of environmental conditions among all candidate sites, subject to a limit on the number of sites that can be selected [50,103]. It uses a dissimilarity matrix to characterize the differences between each pair of sites: thus, it can be adapted to generate prioritizations that ensure a representative sample of genetic diversity among sites, using a genetic distance matrix instead of environmental dissimilarity.	[50,77,78,104]

# Box 1. Dispersal estimates and their potential usefulness in spatial conservation prioritization

Intraspecific genetic data offer various ways to estimate dispersal in organisms and habitats that are
 otherwise difficult to study using direct observations, such as tiny fish and invertebrate larvae that have the
 potential to disperse widely on ocean currents.

312 Parentage analysis - whereby offspring are assigned to parents based on their DNA - can be used to directly 313 detect dispersal events [78]. In one example, D'Aloia et al. [36] genotyped over 7,000 individuals of the 314 neon goby *Elacatinus lori* and used parent-offspring matches to estimate the species' dispersal kernel on 315 the Belize barrier reef (Fig. I-A-B). They found that most larvae dispersed less than 2 km from their parents, 316 despite larvae spending nearly one month dispersing. Like most parentage studies, this was constrained to 317 a relatively small spatial area and required a large amount of sampling that will not be feasible to undertake 318 for all species of interest in SCP. However, follow-up studies have corroborated this strongly limited 319 dispersal pattern. For example, genetic sibship reconstruction revealed that full siblings are spatially 320 arranged as predicted by the parentage dispersal kernel [105] and genetic assignment tests at the scale of 321 the species' range revealed a low frequency of long-distance dispersal events [106]. The congruence 322 between multiple genetic estimates of dispersal in E. lori is promising for the application of more feasible 323 genetic-based estimates of dispersal in other species.

325 Figure I. Using genetic-based dispersal estimates to inform spatial conservation prioritization. (A) A larva of the neon goby

# Box 2. Spatial conservation prioritization as a framework to place new

conservation areas

Spatial conservation prioritization (SCP) can be treated as a mathematical problem involving the spatial distribution of biodiversity features (e.g. species, indexed by j = 1, ..., S) and conservation costs in a set of sites indexed by i = 1, ..., N.  $r_{ij}$  indicates the spatial occurrence (binary variable) or abundance (continuous variable) of biodiversity feature j in site i. In one of the several possible types of SCP problems, the minimum set coverage [71], the mathematical formulation involves two equations:

$$min\left(\sum_{i=1}^{N} c_{i}x_{i} + b\sum_{i=1}^{N} \sum_{h=1}^{N} x_{i}(1-x_{h})cv_{ih}\right)$$
(1)

$$\sum_{i=1}^{N} r_{ij} x_i \ge T_j \ \forall j \tag{2}$$

where  $x_i$  is the unknown variable indicating whether a site is selected for protection ( $x_i = 1$ ) or not ( $x_i = 0$ ). Solving the problem means finding the vector of  $x_i$ 's that satisfies the two equations.

Equation (1) states that the total cost of protection should be minimized. The total cost is the sum of two 338 339 terms: the first term is the sum of the site-specific costs of protection,  $c_i$ 's, which can be defined as the 340 monetary costs required to purchase the sites, as the opportunity costs of other excluded territorial uses or, in the absence of such information, simply as the surface area of the sites. The second term of equation 341 (1) is used to limit the spatial fragmentation of the solution by introducing a boundary costs cv<sub>ih</sub>, which is 342 343 typically the length of the physical boundary between site i and h [5]; more simply, when sites have the 344 same shape and size and are placed on a regular grid,  $cv_{ih} = 1$  for adjacent sites and 0 otherwise. For two 345 adjacent sites, the cost is paid when site *i* is protected but site *h* is not ( $x_i = 1$  and  $x_h = 0$ ). The "boundary 346 length modifier" b is set according to the degree of fragmentation that is deemed acceptable (a lower b 347 leads to a more fragmented solution).

- Equation (2) constrains the solutions to sets of sites that include a minimum target proportion  $T_i$  of the geographical range of each species.  $T_i$  is set according to ecological considerations: for example, species with smaller ranges are given higher targets because they might be at higher risk of extinction than species with larger ranges [61].
- 352 The SCP problem can be solved using exact or heuristic methods implemented in several software packages
- 353 [5,107,108]. The solution is a list of priority sites for the creation of new conservation areas (**Figure I**).

# Box 3. Retaining adaptive genetic diversity to foster persistence under uncertain future conditions

360 Prioritizing portfolios of genetic combinations increases the probability that "winning" combinations can 361 persist during periods of environmental change [71]. Depending on the genetic structure of the species, 362 targeting sites with high within-site adaptive genetic diversity or sites with populations adapted to different 363 local conditions will help build conservation area networks that retain the genetic diversity of species. 364 An example of prioritizing within-site diversity is given by Xuereb et al. [74]. They used environmental 365 association analysis to identify 51 SNPs associated with mean bottom temperature in the California sea 366 cucumber Parastichopus californicus living in the coastal seas of British Columbia (Canada). Then, they used 367 within-site heterozygosity at these putatively adaptive SNPs as a biodiversity feature in spatial conservation 368 prioritization (SCP), which led to the selection of sites in the northern region of the study area. In a second 369 prioritization exercise, they used the frequency of warm-temperature-associated alleles as a biodiversity 370 feature, which led to the selection of sites in the southern region. These results illustrate a trade-off 371 between prioritizing specific alleles versus prioritizing genetic diversity. 372 The second option is protecting a portfolio of sites with a diverse set of adaptations. Hanson et al. [84] 373 genotyped three amphibian species living in the Iberian peninsula at several thousand SNPs. Using outlier 374 detection and environmental association analyses with climatic and soil variables, they identified several

putatively adaptive loci in each species. They then identified sets of populations sharing similar adaptations
(adaptive units [24]) by applying genetic clustering techniques to these putatively adaptive loci and used

377 them as distinct biodiversity features in SCP. This allowed them to identify a set of complementary priority

areas for the conservation of adaptive genetic diversity at the species level.

When selecting different sites, it is important that the genetic variants that may be favorable under futureconditions will be able to spread to the other sites. For this reason, it is advisable to combine the

381	prioritization of genetically diverse sites with estimates of dispersal to build adaptation networks capable of
382	exchanging favorable genetic variants when needed [71]. Various approaches are available to integrate this
383	type of information in SCP (see main text). It should be noted, however, that prioritizing portfolios of
384	genetic combinations is still subject to the difficulties of correctly characterizing adaptive genetic diversity.

# (end of Box 3)

#### 386 **GLOSSARY**

- Adaptive genetic diversity. The genetic diversity that is estimated at adaptive genes, i.e. those that have an
   effect on fitness [27]
- Biodiversity feature. A component of biodiversity (e.g. species, alleles, ecosystems) that can be mapped in
  a landscape.

391 **Census population size.** The count of individuals in a population, often restricted to adult individuals.

- 392 Comprehensiveness. The degree to which a set of conservation areas includes all elements of biodiversity393 features [51].
- **Demographic connectivity.** The relative contribution of dispersal to population dynamics.
- 395 Demographic rescue. A decrease in population extinction probability owing to the simple addition of396 immigrants.
- **Dispersal kernel.** The statistical distribution of dispersal distances in a population.
- 398 Dispersal matrix. A dispersal matrix describes the probability of dispersal between a set of sites in the
- landscape. Each element of the dispersal matrix is the dispersal probability from site *j* to site *i*, which may
- 400 be different from the dispersal probability from site *i* to site *j* (asymmetric dispersal).
- 401 **Ecological niche model.** A statistical model linking the spatial occurrence of a biodiversity feature to a set of
- 402 environmental variables. It is often used to predict species occurrences in places where no data are
- 403 available (spatial prediction) or in the future (forecasting).

404	Effective population size.	The size of an ideal	population	experiencing the sar	ne rate of genetic drift or
-----	----------------------------	----------------------	------------	----------------------	-----------------------------

- inbreeding as the population under study. The ideal population is usually a closed population of constant
- 406 size with discrete generations and a Poisson variance in reproductive success between individuals.
- 407 Environmental association analysis. A statistical approach to identify genetic variants strongly associated
   408 with specific environmental conditions.
- 409 **Genetic rescue.** A decrease in population extinction probability owing to gene flow.
- 410 Inbreeding depression. Reduced fitness of offspring with related parents, often due to deleterious
- 411 recessive alleles that become expressed in homozygous state.
- 412 **Outlier test.** A statistical approach to identify loci involved in local adaptation by screening for alleles that

show unusually high genetic differentiation among populations, i.e. outside of the distribution expected

414 under neutrality.

415 Neutral genetic diversity. The genetic diversity estimated at putatively neutral genes, I.e. those that do not
416 have any direct effect on fitness. This type of genetic diversity is selectively neutral and is useful to estimate
417 dispersal and population size [27].

### **Outstanding questions**

What is the risk of disregarding intraspecific genetic data in spatial conservation prioritization (SCP) for biodiversity persistence? Conservation decisions have been and will be made in the absence of intraspecific genetic data, especially when they are too demanding to be collected. In what cases is it worth spending more time and money to collect genetic data?

As intraspecific genetic data are still lacking for many species, to what extent can they be replaced by surrogate information such as environmental variables in setting spatial conservation priorities?

What is the best method to spatialize genetic data to obtain information for unsampled sites?

How much more land and sea surface area will have to be protected to represent intraspecific genetic diversity? Previous studies showed that moderate extension of the current global system of conservation areas (CAs) would be sufficient to represent phylogenetic and functional diversity, but would this be true for intraspecific genetic diversity?

What is the impact of uncertainty in genetic data on the outcome of SCP? When uncertain genetic data are used in conjunction with other types of information to represent additional constraints to prioritization, the results risk being economically inefficient or unfavorable for conservation.

What is the risk of integrating intraspecific genetic data for some species only? Maximizing genetic diversity of one species can lower diversity of others. How would one select the species to collect genetic data on?

Ref	Citation	Number of species	Molecular markers <sup>a</sup>	Integration of genetic data <sup>b</sup>	SCP method <sup>c</sup>	Genetic metrics <sup>d</sup>	Inference of information in unsampled sites
[1]	Moritz (2002)	10	mtDNA	ED	Environmental diversity	Nei's [26] genetic distance averaged across species	Not performed. Only sampled sites were included in the prioritization.
[2]	Bonin et al. (2007)	2	AFLP	GM	Exhaustive search	Proportion of polymorphic loci Population adaptive index [2]	Not performed. Only sampled sites were included in the prioritization.
[3]	Thomassen et al. (2011)	7	AFLP, msat, nuDNA	ST	ResNet	Nei's [26] genetic distance F <sub>ST</sub> φ <sub>ST</sub>	Generalized dissimilarity modelling [27]
[4]	Diniz-Filho et al. (2012)	1	msat	AL	Simulated annealing		Not performed. Only sampled sites were included in the prioritization.
[5]	Taberlet et al. (2012)	39	AFLP	AL	ZONATION		Not needed. Sampling was performed using a regular grid
[6]	Vasconcelos et al. (2012)	30	None <sup>e</sup>	CU	ZONATION		Ecological niche model with MAXENT [28]
[7]	Beger et al. (2014)	1	msat	ST, CM	MARXAN	Genetic clusters identified with STRUCTURE [29]	Allelic richness and local <i>F</i> <sub>ST</sub> were interpolated in ARCGIS.
						Allelic richness	Asymmetric migration rates were
						Local <i>F</i> <sub>ST</sub> estimated with GESTE [30]	applied to proximate neighborhood identified using Thiessen polygons
						Asymmetric recent migration rates estimated with BAYESASS+ [31]	
[8]	Schlottfeldt et al. (2015)	1	msat	AL, GM	Multi- objective Evolutionary	Expected heterozygosity	Not performed. Only sampled sites were included in the prioritization.

**Table S1.** List of published studies integrating intraspecific genetic data in spatial conservation prioritization

					Algorithms (MOEA, [36])	p-value of $\chi^2$ test for Hardy-Weinberg equilibrium	
[9]	Diniz-Filho et al. (2016)	1	msat	AL	Exhaustive search		Not performed. Only sampled sites were included in the prioritization.
[10]	Hermoso et al. (2016)	4	Msat, mtDNA	CU	Marxan		Generalized dissimilarity modelling [27]
[11]	Carvalho et al. (2017)	33	mtDNA	CU	Zonation, Marxan		Phylogeographical interpolation with Phylin [32]
[12]	Hanson et al. (2017)	27	AFLP	ED	Raptr	Gower's [33] distance	Not needed. Sampling was performed using a regular grid
[13]	Nielsen et al. (2017)	5	mtDNA	ST	MARXAN	Haplotype diversity	Inverse distance-weighting
						Nucleotide diversity	
						Number of private haplotypes	
						Local genetic differentiation	
[14]	Hanson et al. (2018)	1	AFLP	ED	Raptr	Gower's [33] distance	Not needed. Sampling was performed using a regular grid
[15]	Vasconcelos et al. (2018)	23	mtDNA	CU	ZONATION		Ecological niche model with MAXENT [28]
[16]	Paz-Vinas et al. (2018)	6	msat	AL	MARXAN	Allelic richness	Generalized linear models for spatial
						Private allelic richness	stream networks [35,36]
						Jost's [34] differentiation	
[17]	Rosauer et al. (2018)	11	None <sup>e</sup>	CU	MARXAN		Lineage distribution model [37]
[18]	Hanson et al. (2019)	9	AFLP	СМ	Prioritizr	Landscape resistance estimated from Nei's [26] genetic distance between sites	Not needed. Sampling was performed using a regular grid

[19]	Diniz-Filho et al. (2020)	1	msat	AL	Exhaustive search		Not performed. Only sampled sites were included in the prioritization.
[20]	Hanson et al. (2020)	3	SNP	CU, ST	Prioritizr	Mean individual heterozygosity	Thin plate splines; phylogenetic interpolation with PHYLIN [32]
[21]	Nielsen et al. (2020)	5	mtDNA, SNP	ST	Marxan	Nucleotide diversity	Inverse distance-weighting
						Percentage of private alleles	
						Percent of outlier SNPs	
[22]	Hanson et al. (2021)	10	msat	ED	Environmental diversity	Jost's [34] genetic differentiation	Not performed. Only sampled sites were included in the prioritization.
[23]	Phair et al. (2021)	1	SNP	ST	Marxan	Nucleotide diversity	Inverse distance-weighting
						Expected heterozygosity	
						Allelic richness	
						Number of shared SNPs and private SNPs	
						Proportion of outlier SNPs	
[24]	von Takach et al. (2021)	1	SNP	AL	Prioritizr		Not performed. Only sampled sites were included in the prioritization.
[25]	Xuereb et al. (2021)	1	SNP	GM	Prioritizr	Expected heterozygosity	Inverse distance-weighting
						Local F <sub>ST</sub>	
						Adaptive score [38]	
						Population adaptive index [39].	

#### Notes

The table includes only papers using intraspecific genetic data to obtain information that is used to define the input of a spatial conservation prioritization problem. The table was prepared starting from papers known to the authors and searching within the literature cited in them.

<sup>a</sup> Type of molecular marker used: mitochondrial DNA (mtDNA), nuclear DNA (nuDNA), amplified fragment length polymorphisms (AFLP), microsatellites (msat), single nucleotide polymorphisms (SNP)

<sup>b</sup> Methods used to integrate intraspecific genetic data in spatial conservation prioritization: alleles (AL), conservation units (CU), genetic metrics (GM), split taxa (ST), environmental diversity (ED). See **Table 1** in the main text for description of the methods

<sup>c</sup> Method or software package used to perform spatial conservation prioritization (SCP): environmental diversity [40], MARXAN [41], ZONATION [42], PRIORITIZR [43], RAPTR [14], RESNET [44], MOEA (multi-objective evolutionary algorithms, [45]). Exhaustive search means that all the possible combinations of sites were considered.

<sup>d</sup> Genetic metrics used in the prioritization either as biodiversity features (GM method), to split taxa layers (ST methods), as a distance or dissimilarity metric in the environmental diversity method (ED) or to integrate information on connectivity.

<sup>e</sup> ESUs had been identified in other studies
