16 ABSTRACT— Squamate faunas from the early Eocene of Europe are rare. A newly  
17 discovered early Eocene (MP 10–11) Cos locality in southwestern France has yielded an  
18 assemblage of anguimorph lizards that sheds light on the early evolution of this group.  
19 Among them is a new glyptosaurine lizard *Sullivania gallica* gen. et sp. nov., based on frontal  
20 material with a unique pattern and distribution of polygonal osteoderms that is distinct from  
21 that of the middle and late Eocene *Placosaurus* from France. It slightly resembles the  
22 stratigraphically older glyptosaurine *Gaultia silvaticus* from the earliest Eocene of North

23 America, but differs from it in several aspects. Although fossils of some members of  
24 Glyptosaurinae (sensu this paper; Glyptosaurini in previous taxonomies – Glyptosaurinae is  
25 returned to the family level originally proposed by Marsh) have been documented rarely from  
26 the middle and mainly from the late Eocene of Europe, they are virtually unknown from the  
27 early Eocene. One isolated osteoderm is referred only to *Anguioidea* indet. This specimen  
28 resembles osteoderms seen in *Anguinae*, provided that the absence of tuberclulate  
29 ornamentation is not caused by abrasion.

30 Varanoids are represented by an isolated frontal referred to *Palaeovaranidae* indet. It  
31 possesses a complex ornamentation composed of mounds on the dorsal surface. A maxilla is  
32 identified as an indeterminate varanoid based on the plicidentine infolding along the bases of  
33 the preserved teeth.

34 Although incomplete, this Cos lizard assemblage is an important and rare discovery  
35 that provides a glimpse into the ecosystems and paleobiodiversity of the early Eocene in  
36 western Europe.

## INTRODUCTION

41 The Cos fissure fill was the first “phosphatière” discovered in the Quercy by J. A.  
42 Poumarède in 1865 (Pulou, 1980), but one of us (DV) discovered vertebrate fossils in this  
43 locality only more recently. Cos constitutes the seventh pre-upper Eocene locality of  
44 Phosphorites du Quercy [for others see Astruc et al. (2003): Pasturat (MP 8+9), Viélase and  
45 Cazals (both MP 10–11), Cuzal, Parnac and Grélaou (all MP 13)]. Based on the studies of the  
46 primates (Godinot et al., 2021) and rodents (Vianey-Liaud et al., 2022), the vertebrate fauna of  
47 the Cos site has been dated as MP 10–11, a zone that spans the late Ypresian and early Lutetian.

48 Thus, it corresponds to the Early Eocene Climatic Optimum (EECO; see Inglis et al., 2020),  
49 which is dated as 53.3 to 49.1 Ma. EECO was a time of major climatic and environmental  
50 change caused by perturbations to the global carbon cycle (Hyland et al., 2017). This makes the  
51 Cos locality particularly important because the early Eocene terrestrial fossil record in Europe  
52 is poorly known.

53         There have been only a few early Eocene sites where assemblages of amphibians and  
54 reptiles have been described. These include: Dormaal (MP 7) in Belgium (Augé, 1990, 1992;  
55 Augé & Smith, 1997, 2002; Augé et al., 2022; Čerňanský et al., 2022; Folie et al., 2013;  
56 Hecht & Hoffstetter, 1962; Sullivan et al., 2012); Silveirinha (~MP 7) in Portugal (Rage &  
57 Augé, 2003); the early Eocene of (different localities in) Catalonia, Spain (Bolet, 2017); and  
58 some localities in France, notably Prémontré (~MP 10; Augé, 2003, 2005; Augé et al., 1997),  
59 Mutigny (MP 8–9; Čerňanský et al., 2020; Augé et al., 2022) and La Borie (MP 8–9) (Laurent  
60 et al., 2010). There are also some other famous early Eocene localities, which yielded snakes,  
61 turtles, and crocodiles, such as Monte Bolca, Italy (Seghetti et al., 2022) and the English  
62 localities in Isle of Sheppey, Bracklesham, and Kingston (Owen, 1841, 1850; Georgalis &  
63 Joyce, 2017; Smith & Georgalis, 2022). In contrast, such assemblages are relatively well-  
64 known for the middle and late Eocene in Europe, in part thanks to exceptional localities such  
65 as Geiseltal and Messel in Germany (Čerňanský & Smith, 2018, 2019 Keller, 2009; Smith et  
66 al., 2018; Sullivan et al., 1999; Villa et al., 2022) and in some of the localities of Phosphorites  
67 du Quercy in France (Augé, 2005; Čerňanský et al., 2015; Georgalis et al., 2021). Here we  
68 report on the fossil anguimorph lizards from the newly discovered Cos locality, on the  
69 southern Quercy limestone plateau, southern France.

70         Modern Anguimorpha includes Anguidae, Diploglossidae, Xenosauridae,  
71 Helodermatidae, Lanthanotidae, Varanidae and Shinisauridae. Anguidae represent a  
72 diversified and widely distributed group of reptiles of which Anguinae is the most derived

73 clade (Augé, 2005; Uetz et al., 2023). Although there have been recent alterations to  
74 phylogenetical conceptions that have been stable for decades (e.g., Burbrink et al., 2020;  
75 Pyron et al., 2013) and the position of Diploglossidae is still debated (as a subclade of  
76 Anguinae, Conrad 2008; Gauthier et al., 2012; Pyron et al., 2013; as a distinct clade outside of  
77 Anguinae, Burbrink et al., 2020; Zheng & Wiens, 2016), aside from Anguinae three other  
78 extant clades were traditionally included in Anguinae. These are Gerrhonotinae, Anniellinae,  
79 and the extinct Glyptosaurinae (sensu McDowell & Bogert, 1954; see Gauthier et al., 2012;  
80 Georgalis et al., 2021; Sullivan, 1979, 2019; note, however, that if Diploglossidae is treated at  
81 the family level, then Glyptosaurinae must also be returned to the family level originally  
82 proposed by Marsh, 1872, as members of this clade are much morphologically distinct  
83 compared to Anguinae, see below). Glyptosaurinae (sensu McDowell & Bogert, 1954)  
84 inhabited North America, Europe, and Asia and are known from the Cretaceous to the late  
85 Paleogene-Oligocene (Čerňanský and Augé, 2019; Conrad & Norell, 2008; Keller, 2009;  
86 Sullivan, 1979, 2019). This clade was traditionally divided into the tribes Glyptosaurini and  
87 the paraphyletic “Melanosaurini” (Cicimurri et al., 2016; Estes, 1983; Sullivan, 1979, 2019).  
88 Among the former, *Placosaurus* Gervais, 1848–1852 is the only known member of the tribe  
89 in Europe (see Sullivan, 2019; Sullivan & Augé, 2006; Sullivan et al., 2012). It is represented  
90 by two currently valid species from the late Eocene of France (only the two species are  
91 definitely members of the genus, whereas the others are only questionably referred to  
92 *Placosaurus*), type of which are cranial remains. This is very low diversity compared to the  
93 North American glyptosaurine genera such as *Glyptosaurus* Marsh, 1871, *Paraglyptosaurus*  
94 Sullivan, 1979, *Helodermoides* Douglass, 1903 and *Gaultia* Smith, 2009 (Smith, 2009, 2011;  
95 Sullivan, 1979). Moreover, although members of the clade were well documented from the  
96 early Eocene in North America, glyptosaurines are largely unknown for most of the early and  
97 middle Eocene of Europe (Sullivan, 2019). In the early Eocene of Europe, the glyptosaurine

98 taxon ?*Placosaurus ragei* Sullivan, Augé, Wille & Smith, 2012 and *Placosauriops*-like  
99 “melanosaurine” are known from Dormaal (MP 7). The Dormaal glyptosaurine ?*Placosaurus*  
100 *ragei* is known based on the holotype dentary and a referred parietal. However, the current  
101 taxonomy of species of *Placosaurus* is based on the morphology of the frontal (Sullivan &  
102 Augé, 2006), so its generic assignment is questionable (Sullivan et al., 2012). Indeterminate  
103 material (frontal and parietal) of glyptosaurines is also described from Silveirinha (~MP 7;  
104 Rage & Augé, 2003). In Asia, *Stenoplacosaurus mongoliensis* (Sullivan, 1979) was described  
105 from the middle Eocene of Mongolia (Sullivan & Dong, 2018; *Helodermoides mongoliensis*  
106 in Sullivan 1979; *Placosaurus mongoliensis* in Sullivan and Augé, 2006). This taxon is also  
107 based on the frontal morphology. Additionally, several isolated osteoderms of glyptosaurines,  
108 plausibly belonging to this early Eocene lineage, were described from the early Oligocene of  
109 Mongolia (Čerňanský & Augé, 2019). Thus, Glyptosaurinae has a continuous history in Asia  
110 at least until the Oligocene, although disappeared in Europe at the Eocene–Oligocene  
111 boundary (Rage, 2013). However, their early history in Europe remains largely unknown. All  
112 the specimens in this study are from the Cos fissure fill, Phosphorites du Quercy, 2.5 km  
113 southwest of Caylus, France.

118 collection.

119

120

## MATERIAL AND METHODS

121

122 **Specimens examined and terminology**

123 The studied material is housed at the University of Montpellier, cataloged under  
124 individual UM-COS-numbers. The standard anatomical orientation system is used throughout  
125 this paper, and terminology describing individual bone structures is based on Rage & Augé  
126 (2010).

127

## 128 **X-ray Microtomography, Three-Dimensional Visualization, Photography and** 129 **Reconstruction**

130 The fossil specimens were imaged on micro-computed tomography (CT) at the micro-  
131 CT facility, Slovak Academy of Sciences in Banská Bystrica, Slovakia, using a Phoenix mikro-  
132 CTv|tome|x L240. The settings were as follows: VxSize = 0.01999999; Current = 150; Voltage  
133 = 130; Inttime = 20000; Average = 2; Steps = 1600; Steps360 = 2200; Filter = 0.1 mm Cu. The  
134 images were recorded over 360°. The CT data sets were analysed using VG Studio Max 3.1.  
135 and Avizo 8.1. The photographs of the UM-COS-1011 maxilla were taken with a Leica M205  
136 C binocular microscope with an axially mounted DFC 290 HD camera; software: LAS (Leica  
137 Application Suite) 4.1.0 (build 1264). The image processing program ImageJ (Schneider et al.,  
138 2012) was used for measurements. For frontal reconstruction, the missing areas were restored  
139 by mirror imaging of the holotype and paratype, and estimation of the posterior portion is based  
140 on the preserved paratype. The holotype (UCMP 216000) and paratype (UCMP 150966) of  
141 *Gaultia silvaticus* were drawn from photographs published by Smith (2009: fig. 18). The  
142 holotype of *Stenoplacosaurus mongoliensis* (AMNH 6669 left frontal) was drawn based on  
143 photographs published by Sullivan & Dong (2018: fig. 1).

144

## 145 **Geological Setting and Associated Fauna**

146 Located in the southern part of the ‘Causses du Quercy’ plateau, the fissure fills of Cos  
147 lie within the Middle Jurassic (late Bajocian/Bathonian) marine limestones of the Cajarc

148 Formation (44°13'11.20"N, 1°44'58.21"E; Fig. 1). The site is a northwest-southeast trending  
149 large excavation (~80 m x 50 m), with the phosphate ore deposits nearly depleted. Positioned  
150 at the eastern end of the excavation, the fossiliferous fissure-fill at Cos is unlike those found in  
151 other localities of the Phosphorites du Quercy in that the strata that contain the fossiliferous unit  
152 are composed of small beds of granular and porous stratified limestones, alternating with red  
153 clays containing small pisolites. There are still uncertainties about geometric and stratigraphic  
154 relationships between the limestones and the interbedded red clays. There are few scattered  
155 vertebrate fossils through the entire section. The fauna recovered includes amphibians,  
156 squamates, crocodylians, birds, and more than twenty mammal species among which only  
157 primates and rodents have been studied (Godinot et al., 2021; Vianey-Liaud et al., 2022). All  
158 of the specimens described herein are from the Cos fissure fill of the Phosphorites du Quercy  
159 region and are early Eocene (MP 10–11 interval) in age.

160

## 161 SYSTEMATIC PALEONTOLOGY

162

163 **Taxonomic note**—If most clades previously considered subfamilies of Anguinae sensu  
164 Camp, 1923 – viz., Anguinae, Anniellinae and Diplglossinae – are now considered taxa at the  
165 family level, and there is no evidence that glyptosauroids are part of any of those radiations, then  
166 Glyptosaurinae sensu McDowell & Bogert, 1954 must also be returned to the family level  
167 originally proposed by Marsh (1872). Accordingly, we consider Glyptosauridae Marsh, 1872  
168 to contain the subfamilies Melanosaurinae Sullivan, 1979, which is paraphyletic, and  
169 Glyptosaurinae Marsh, 1872, which correspond to the tribes Melanosaurini and Glyptosaurini  
170 of Sullivan (1979). The name “Placosauridae” (e.g., Cope, 1877; Kuhn, 1940) is a junior  
171 synonym of Glyptosauridae (Estes, 1983; McDowell & Bogert, 1954), so it does not affect  
172 our new status.

GLYPTOSAURINAE Marsh, 1872 (sensu this paper)

*SULLIVANIA* gen. nov.

**Type species**— *Sullivania gallica* sp. nov.

**Etymology**—The genus is named in recognition of the American paleontologist Robert M. Sullivan for his valuable contributions to glyptosaurine morphology, paleobiogeography, and paleobiodiversity.

**Diagnosis**—As for *Sullivania gallica* sp. nov., the only known species.

*Sullivania gallica* sp. nov.

(Figs. 2, 3, 4A)

**Etymology**— The specific epithet *gallica* is based the Latin “gallicus” in reference to the country of France, where the fossils were found.

**Holotype**— UM-COS-1001, greater anterior portion of fused frontals.

**Paratypes**— UM-COS-1000, incomplete right frontal; and UM-COS-1003, posterior region of the right frontal.

**Differential Diagnosis**— Glyptosaurine differing from all other Glyptosauridae in having unique pattern of irregular cephalic osteoderms covering the frontal where the first two

198 anterior central osteoderms straddle the midline, and are coalesced or fused, narrow,  
199 anteroposteriorly elongate, leaf-shaped, reaching only slightly further anteriorly than the  
200 much larger, anteroposteriorly elongated lateral osteoderm with rounded lateral margin. This  
201 is in a sharp contrast to several wide, chevron-shaped osteoderms in *Gaultia* (in *Sullivania*,  
202 only the second lateral left and right osteoderms appear expanded medially, having contact in  
203 the mid-line) and high and regular division of dermal armor into discrete hexagonal  
204 osteoderms in *Placosaurus*, *Stenoplacosaurus*, *Glyptosaurus*, *Paraglyptosaurus*,  
205 *Helodermoides*, and *Eoglyptosaurus*. It is further distinguished from all other glyptosaurines  
206 by the following combination of features of the frontal: (1) osteoderms are apically flat, as  
207 *Gaultia*, not thick as in *Placosaurus*, and not inflated (or bulbous) as in *Glyptosaurus*,  
208 *Eoglyptosaurus*, *Helodermoides* and *Stenoplacosaurus*; (2) generally rather fewer osteoderms  
209 contra numerous in *Placosaurus* (especially *Placosaurus estesi*), *Glyptosaurus*,  
210 *Eoglyptosaurus* and *Helodermoides*; (3) concave lateral margins unlike in the North American  
211 *Helodermoides*; (4) posterolateral process not distinctly laterally expanded and expansion  
212 includes only the posterior 1/3 of the bone, unlike in *Placosaurus estesi* and  
213 *Stenoplacosaurus*, in which the lateral expansion starts at the posterior 2/3 of the bone; and  
214 (5) frontals fused only in the late ontogeny (fusion is present only in the larger, robust  
215 specimen). In *Stenoplacosaurus*, the frontals are unfused.

216 **Type locality and horizon**—Cos, fissure fill in the Quercy region (southwestern France);  
217 early Eocene (MP 10–11 interval); the species is so far known exclusively from the type  
218 locality.

## 219 **Description**

220 **Frontal**—The holotype (UM-COS 1001, Fig. 2) represents fused right and left  
221 frontals (although traces of fusion are still recognizable). Its lateral margin is slightly concave  
222 and gradually widens posteriorly. The dorsal area surrounding the mid-orbital margin slopes

223 slightly toward the orbit. The posterior portion of the bone is missing due to breakage. Thus,  
224 only the anterior and mid-portions are preserved. The maximum width of the preserved  
225 frontal is 11.7 mm. The element is more robust than UM-COS-1000 and is inferred to be from  
226 a larger (older) individual. The external surface is largely covered by ornamented osteodermal  
227 shields of various irregular, polygonal to roughly ovoid outline. They are completely fused to  
228 the underlying bone and are separated one from another by sulci (note, however, that it is not  
229 clear whether the osteodermal boundaries coincide with the epidermal scale boundaries). The  
230 ornamentation is formed by small rounded discrete tubercles that are regularly and densely  
231 arranged. The exception is in its anterior section, where a broad semi-elliptical smooth surface  
232 is located. It forms the articular facet for nasal (which is preserved on the right side). Here, the  
233 bone expands into a prominent, pointed anteromedial (nasal) process. The process is  
234 triangular. The anterolateral process is only partly preserved on the right side, but this  
235 preserved portion extends much less anteriorly than the anteromedial one. Posterior to this,  
236 three osteodermal shields are present. The first one is an anterior central shield. Here, the left  
237 and right frontal are fused along the mid-line. Thus, the first two anterior osteoderms straddle  
238 the midline and are coalesced or fused into the one. The first central shield is narrow,  
239 anteroposteriorly elongate and more or less leaf-shaped. It extends only slightly more  
240 anteriorly than the lateral shields. The lateral osteodermal shields are large, much larger than  
241 the central one (completely preserved on the right side). The medial margin of the lateral  
242 shields is V-shaped, whereas the lateral margin is rounded. The medial peak of V-shaped  
243 medial margin indicates a mediolateral short sulcus, where the first anterior central shield  
244 ends. Posterior to the sulcus in the midline, there is a second central shield. The more  
245 posterior region bears several cracks and thus, it is difficult to properly identified the original  
246 borders of the osteodermal shields (Fig. 2A, B). However, it appears that the both second  
247 lateral shields are medially expanded (best visible on the left side). The left and right shields

248 seem to have a short medial contact. If this is the case, these second lateral osteoderms are  
249 mediolaterally wide rather than anteroposteriorly long (in contrast to the first lateral shield).  
250 In this case, the second central osteodermal shield has truncated appearance of the posterior  
251 portion due to this contact and thus, being trapezoidal in shape.

252 In ventral view, a large and robust frontal cranial crest (*crista cranii frontalis*) is  
253 visible. Its anterior portion is expanded forming a well-defined and rounded prefrontal  
254 (=subolfactory) process. It is, however, only partly preserved (its end is damaged; Fig. 2C).  
255 The anteromedial margin of this crest is thin and sharp. Posteriorly, it widens, gradually  
256 diminishing dorsally. The anterior portion of the frontal crest, anterior to the subolfactory  
257 process, is less deep, forming a sharp, medially directed ridge. The right and left branches join  
258 together in the anterior mid-line, forming a sharp angle. Note, however, that there is the  
259 matrix that is still adhering to the ventral side of the frontal between the anterior portions of  
260 the left and right frontal cranial crests. It obscures much of the medial ventral surface of the  
261 frontal. In the anterior region, lateral to the frontal crest (including its lateral surface), a large  
262 facet for the prefrontal is located (the right one is preserved; Fig. 2D). Prefrontal and  
263 postfrontal are not in a contact, and did not exclude the frontal from the orbital border.

264 **UM-COS-1000 and UM-COS-1003 (paratypes)**—UM-COS-1000 (Fig. 3A-F) is a  
265 nearly complete right frontal, with only the anterior end broken. The maximum  
266 anteroposterior length of this incompletely preserved element is 15 mm. It is robust, although  
267 less than the holotype. UM-COS-1003 (Fig. 3G, H) represents the posterior portion of the  
268 right frontal and this specimen is much more robust than the UM-COS-1000. The  
269 posterolateral section of UM-COS-1000 protrudes into a short, but robust, posterolateral  
270 process (the expansion starts in the posterior 1/3 of the bone). Here, the bone is widest – the  
271 maximum mediolateral width of this part of the bone is 9.1 mm. Further anteriorly, the frontal  
272 narrows and the lateral margins are slightly concave. Thus, the bone appears to be narrowest

273 at about mid-orbit (the minimum width of the single right frontal in this area is 5.9 mm). The  
274 external surfaces of both specimens are almost completely covered by tuberculated  
275 osteoderms of various irregular, polygonal (rhomboidal, hexagonal) to roughly ovoid outlines.  
276 The osteoderms are completely fused to the frontal and separated one from another by sulci.  
277 The ornamentation is formed by small rounded discrete tubercles that are regularly and  
278 densely arranged. The osteodermal shields on the posterior portion in UM-COS-1000, close to  
279 the more or less straight contact with the parietal, are weakly ornamented. Only few tubercles  
280 are present in this section on an otherwise smooth surface; however, the dorsal surface in this  
281 region seems to be slightly eroded. The posterolateral corner is smooth, although it appears  
282 that some partial covering was originally here but now is lost. The evidence of this is that a  
283 partly preserved medial margin of the shield still has several tubercles. Thus, the posterior  
284 portion of the right frontal possessed four osteodermal shields arranged in a mediolateral row.  
285 Thus, the frontal is relatively broad. These osteoderms are anteroposteriorly long, roughly  
286 trapezoidal except for the third one (Fig. 3B), which has a triangular end due to hexagonal  
287 shape of neighboring osteoderms in the second row. This second posterior row, located  
288 anterior to the first one (at the level of the anterior beginning of the postfrontal facet),  
289 possesses three osteoderms. They differ in shape from those forming the first posterior row,  
290 being polygonal (roughly hexagonal). The same condition is present in UM-COS-1003,  
291 although the ornamentation is strongly developed here. In the mid-region of UM-COS-1000,  
292 there is a shallow light groove close to the orbital margin. This groove extends almost parallel  
293 to this margin (Fig. 3B).

294 In ventral view, a frontal cranial crest can be observed in both specimens. Posteriorly,  
295 it widens, gradually diminishing dorsally. On the lateral side of the crest, a foramen is visible.  
296 The crest fades out at the beginning of the posterolateral process of the frontal (in both  
297 paratypes) and does not continue to the posterior end of the bone. Here, the large rugose facet

298 for the postfrontal is clearly visible laterally. In UM-COS-1003, the wedge-shaped facet for  
299 parietal tab is visible dorsal to the frontoparietal suture. A facet for the prefrontal is preserved  
300 only in UM-COS-1000. The prefrontal and postfrontal are not in a contact, and thus did not  
301 exclude the frontal from the orbital border.

302         **Virtual microanatomy and histology**—The micro-CT scans of the frontals revealed  
303 a bone structure with a very similar internal microanatomy in terms of a vascular network and  
304 spongiosis (Fig. 2E, F; Fig. 3E, F). It revealed a large and complex meshwork of numerous  
305 cavities. They are irregular, bubble-shaped, and some are interconnected. Thus, the bone  
306 appears to be less compact in both axial and coronal sections. Note that the finer  
307 histological details such as growth marks and cell lacunae of the bone are not visible.

308         **Remarks**— UM-COS-1001 is designated as the holotype because it is from a more  
309 mature (adult) individual. The paratypes UM-COS-1000, the nearly complete right frontal,  
310 and UM-COS-10003, the posterior part of the right frontal, are nearly identical, although UM-  
311 COS-1003 is slightly more robust. UM-COS-1000 and UM-COS-10003 have the identical  
312 arrangement of osteoderms where they overlap the holotype UM-COS-1001. They can add to  
313 the diagnosis a unique character state for Glyptosaurinae - the osteoderms on the  
314 posteriormost portion of the frontal are anteroposteriorly elongate and roughly trapezoidal.  
315 Four osteoderms of equal size are arranged in a mediolateral row. The second posterior row  
316 (located anterior to the first row) possesses three osteoderms, which are roughly hexagonal.  
317 Although all frontals are incomplete, preservation of parts shared by all frontals permits for  
318 reconstruction of the missing areas based on mirror imaging of the right and left elements  
319 (UM-COS-1000). The anterior portion is reconstructed based on the UM-COS-1001 (Fig.  
320 2A). The reconstructed image clearly shows that it is very different from the earliest Eocene  
321 North American glyptosaurine *Gaultia*, the late Eocene European *Placosaurus* and the middle  
322 Eocene Asian *Stenoplacosaurus* (Fig. 4).

323 With regard to the virtual microanatomy, microanatomical studies on fossil anguroids  
324 (i.g., anguids) have previously been conducted. These published works deal with parietals of  
325 *Ophisaurus holeci* (Georgalis & Scheyer, 2021), *Ophisaurus spinari* (Syromyatnikova et al.,  
326 2022), and *Pseudopus pannonicus* (Loréal et al., 2023).

327

### 328 **Glyptosauridae indet.**

329 (Figs. 5, 6A-J)

330

331 **Referred Material**—UM-COS-1002, medial portion of left maxilla; UM-COS-1011,  
332 posterior portion of right maxilla; UM-COS-1004 and 1005, cephalic osteoderms and UM-  
333 COS-1006 and 1007, dorsal trunk osteoderms.

334

### 335 **Description**

336 **Maxilla**—Two incomplete maxillae were recovered (Fig. 5), representing much of the  
337 posterior halves of the bone with the posterior ends broken on both specimens. The left  
338 maxilla (UM-COS-1002, Fig. 5A-D) has seven tooth positions with four-and-a-half teeth  
339 remaining in situ. The right maxilla (UM-COS-1011, Fig. 5E-H) has four posterior teeth and  
340 two broken teeth. The nasal process of the maxilla is partly preserved in both specimens,  
341 gradually decreasing in height posteriorly. Its external surface is ornamented with tubercles  
342 and is best preserved in UM-COS-1011. The extent of this tuberculated surface is not well  
343 delineated as the sulci are not recognizable (see Fig. 5A, E and remarks). The supralabial area,  
344 below the ornamented field, is pierced by supralabial foramina (two are preserved in UM-  
345 COS-1002 and one in 1011). In medial view, the supradental shelf is prominent. The shelf  
346 slopes slightly posteroventrally from the level of the third preserved tooth position (counted  
347 from posterior). The dorsal area of the shelf is concave, forming a longitudinal shallow

348 depression for articulation with the jugal. The shelf itself expands medially, and this  
349 expansion (best preserved in UM-COS-1011) reaches its maximum at the level among third  
350 and fifth tooth positions (counted from the posterior end). Here, the contact with the palatine  
351 is present. UM-COS-1002 bears the posterior opening of the superior alveolar foramen (Fig.  
352 5F, H). It is large, elliptical, and located at the level of the fifth tooth position (counted from  
353 posterior).

354         **Dentition**—The tooth implantation is pleurodont. The teeth are heterodont with the  
355 lingual sides of the teeth expanding medially and gradually increase in robustness posteriorly.  
356 The apices of posterior three teeth are blunt, mesiodistally robust, and possess distinct, well-  
357 defined, mesiodistally straight cutting edges. The lingual and labial surfaces of the tooth  
358 apices are distinctly striated. The first preserved anterior tooth is less robust and labiolingually  
359 compressed.

360         **Remarks**— The maxillae from the Cos site may belong to *Sullivania gallica*, but are  
361 here considered Glyptosauridae indet. owing to lack of definitive characters that would allow  
362 positive identification. The maxilla is similar to that of the late Eocene species  
363 *Paraplacosauriops quercyi* in the lateral ornamentation of the surface of the nasal process of  
364 maxilla and the presence of bulbous teeth (see Auge & Sullivan, 2006; Georgalis et al., 2021).  
365 The ornamentation lacks discrete hexagonal/polygonal osteoderms that would clearly indicate  
366 it was a glyptosaurine. Therefore, the maxilla may be from some unknown “melanosaurine”  
367 similar to *Paraplacosauriops*.

368         **Osteoderms**—Four tuberculated osteoderms were recovered from the Cos site (Fig.  
369 6A-J). Two are hexagonal/polygonal in shape (Fig. 6A-E) and two are rectangular/rhombic  
370 (Fig. 6F-M). The former are from the skull and the latter are from the body. The tubercles are  
371 prominent on the cephalic osteoderms and less so on the body osteoderms but this may be an  
372 artifact of preservation. The keel and the smooth overlap surface are absent on the first type of

373 osteoderms. These osteoderms are also slightly thicker than the second (rectangular) type. The  
374 internal surfaces of the cephalic osteoderms are pierced by numerous foramina along with  
375 several grooves and ridges that extend anteroposterly. The rectangular body osteoderms (Fig.  
376 6F-J) are distinguished by a prominent contact surface that is nearly one-third the  
377 anteroposterior length. It is slightly higher than the posterior ornamented portion, from which  
378 it is separated by a transverse groove. The latter is covered by discrete tubercles of various  
379 sizes. A blunt, weak and slightly oblique keel is present midway along the posterior margin of  
380 the osteoderm. The internal surface is pierced by three foramina located in the central region.

381 **Remarks**—Taxonomic assignment of isolated osteoderms below Glyptosauridae is  
382 not possible (de Buffr enil et al., 2010; Estes, 1983; Gauthier et al., 2012; Rage, 1978;  
383 Sullivan, 1979, 2019). Although differences in general shape and absence/presence of the  
384 overlap surface clearly exist among these osteoderms, their positions on the body plays more  
385 likely a major role in this case. Although it seems to be unlikely that these osteoderms belong  
386 to a form for which no other elements have not been recorded in the locality, we do not  
387 necessarily associate them with the frontals described above and identify them only as  
388 Glyptosauridae indet. The hexagonal/polygonal osteoderms strongly suggest that they are  
389 cranial. In the case of their cranial placement, they belong to Glyptosaurinae. However, the  
390 fact that they may pertain to the cheek region of a “melanosaurine” cannot be ruled out. The  
391 rectangular body (trunk) osteoderms could also be equally be attributed to a “melanosaurine.”

392

393

**Anguioidea indet.**

394

(Fig. 6K-M)

395

396

**Referred Material** —One isolated osteoderm UM-COS-1008

397

398 **Description**

399 **Osteoderm**— UM-COS-1008, a single isolated rectangular osteoderm (Fig. 6K-M) is  
400 thin rather than thick (although slightly thicker than the body osteoderms described above),  
401 with a low medial ridge (which is slightly more pronounced in the posterior section)  
402 extending along the entire central region, being restricted to the sculptured region. The  
403 anterior overlap surface is well defined. It occupies about one quarter of the external surface.  
404 The lateral bevel is narrow and the lateral imbrication is weak but present. The posterior  
405 portion of the external surface is weakly ornamented. The ornamentation is formed by pits  
406 and hardly distinguishable ridges diverging from the central region – pits are transformed into  
407 short grooves at the periphery. The internal surface is pierced by several foramina (at least  
408 two of which are visible). Besides these, few short grooves are ridges are located on the  
409 periphery in the mid-section of the osteoderm, but only on one side.

410 **Remarks**—The osteoderm UM-COS 1008 appears to differ from osteoderms of  
411 Glyptosauridae described above by its shape, thickness, length of overlap surface, presence of  
412 lateral bevel, and the apparent absence of typical discrete tubercles forming the external  
413 ornamentation. This specimen resembles osteoderms present in members of Anguinae  
414 (Čerňanský & Klembara, 2017; Estes, 1983; Georgalis et al., 2019; Hoffstetter, 1962;  
415 Williams et al., 2022), provided that the absence of tubercululate ornamentation is not caused  
416 by abrasion or corrosion. The osteoderm appears to be slightly water-worn. The fact that this  
417 osteoderm is thicker might also support glyptosaurid affinity.

418

419 Varanoidea Gray, 1827 (sensu Estes et al., 1988).

420 Palaeovaranidae Georgalis, 2017

421 **Palaeovaranidae indet.**

422 (Fig. 7)

423

424           **Referred Material** — UM-COS-1009, nearly complete frontal.

425

426   **Description**

427           **Frontal**— The nearly complete frontal (Fig. 7) is an unpaired element, missing only  
428 the anterior end and the left posterolateral corner. In the posterior section, the frontal bears  
429 traces of the original midline suture on both ventral and dorsal surfaces (Fig. 7A, B). It is  
430 narrow anteroposteriorly and flares outward posterolaterally on the right side. The frontal is  
431 small, measuring only 4.6 mm along the mid-line, but was slightly longer in life as the  
432 anterior portion is broken off. The lateral margin of the frontal is concave, with the narrowest  
433 part anterior to the mid-orbit region. Although the anterior portion is missing, the frontal  
434 widens anteriorly, based on the lateral flaring of the crista cranii frontalis on the ventral side  
435 (Fig. 7B).

436           The dorsal surface of the frontal is ornamented with irregular small, distinct mounds.  
437 Their structures are complex, having a shrunken (or rumped) appearance with several  
438 longitudinal crests, whereas others are pointed, forming several small spike-like structures  
439 (they are of high relief). The posterior margin, which contacts the parietal, is anteriorly  
440 concave, giving it a slight irregular or wavy appearance in dorsal view (Fig. 7A, B).

441           On the ventral side, the frontal cranial crests are well-developed, forming a prominent  
442 orbital rim. The cranial crests are slightly deeper ventrally in the anterior region where the  
443 ventral margins are distinct. The crests extend to the posterolateral end of the frontal where  
444 they are slightly wider and blunt. They are pierced by three foramina on each side. The left  
445 lateral side preserves a wedge-shaped facet for the prefrontal at the anterior end (Fig. 7C). The  
446 right lateral side bears a distinct facet at the posterior for the reception of the postfrontal  
447 (Fig. 7D). These articular surfaces are separated by a large portion of the orbital margin.

469

470

471

472

**Maxilla**— The nearly complete left maxilla is preserved in matrix, with the lateral side visible (Fig. 8A). The anterior portion is broken. The preserved portion has a maximum anteroposterior length of 10.2 mm and a maximum height of 4.6 mm, measured from the ventral edge of the maxilla to the uppermost extent of the nasal process. The nasal process of the maxilla is rather thin and has a slightly concave smooth surface with a few fractures along the anterior half of the process due to crushing. The posterior margin of the nasal process slopes posteroventrally at an angle of 28° where it ends near a small slit at the level of the last preserved tooth. The external surface of the process is pierced by a series of four large supralabial foramina along the external labial margin of the tooth row. In addition, there are several smaller foramina located anterodorsally to the anteriormost preserved tooth. The maxilla bears five complete teeth and has positions for four others. Posterior to the last labial foramen, four tooth positions are present. The supradental shelf is relative thin, but widens anteriorly (Fig. 8B). It protrudes medially, reaching its maximum at the level between the fourth and fifth tooth position (counted from posterior) because of its contact with palatine. The posterior opening of the superior alveolar canal is large and located at the level of the sixth tooth position (counted from posterior). The medial surface of the preserved portion of nasal process of maxilla is smooth and no nasal crest on the dorsomedial surface can be observed; however, the dorsal portion of the maxilla is fractured.

498 characterized by irregular plate-like osteoderms that cover the skull roof (Sullivan, 1979, 2019).  
499 Thus, isolated glyptosaurine frontals (and parietals) can be identified based on the presence of  
500 hexagonal/polygonal tuberculate osteoderms covering the skull roof. For this reason, the Cos  
501 frontal specimens clearly represents a member of Glyptosaurinae.

502         Until now the only glyptosaurine known from Europe has been *Placosaurus* from the  
503 Eocene (Depéret, 1917; Gervais, 1848-52; Sullivan, 1979; Sullivan & Augé, 2006). Today, it  
504 comprises four species: *Placosaurus rugosus* Gervais, 1848–1852, *Placosaurus estesi* Sullivan  
505 & Augé, 2006, “*Placosaurus*” *europaeus* (Filhol, 1876; based on a dentary with teeth, so its  
506 generic assignment is equivocal; Sullivan & Augé, 2006), and ?*Placosaurus ragei* Sullivan et  
507 al., 2012 (based on a dentary and a referred parietal). Most finds are from the late Eocene  
508 (except for ?*P. ragei*), while some are also known from the late middle Eocene (Lavergne and  
509 Le Bretou, Quercy; Rage 1988 and Augé 2005, Sullivan & Augé, 2006). *Placosaurus* can be  
510 distinguished from the North American glyptosaurine genera *Glyptosaurus*, *Paraglyptosaurus*,  
511 *Proglyptosaurus*, and *Helodermoides* by the following combination of features on frontal  
512 (Sullivan & Augé, 2006): (1) frontals are fused and (2) slightly arched; and (3) cephalic  
513 osteoderms usually form one or two complete rows of hexagonal osteoderms over each orbit.  
514 However, the Cos frontals have a unique distribution of skull osteoderms and therefore cannot  
515 be referred to this taxon or any of the other taxa (Fig. 4).

516         **The early Eocene glyptosaurines compared to post-early Eocene glyptosaurines**  
517 **in Europe**—All glyptosaurine frontals from Cos described here most likely belong to the  
518 same taxon as they have the same flat osteoderm morphology and display similar distribution  
519 pattern on the frontal where they correspond and are similar size. Moreover, they are  
520 comparable in size and come from the same locality. These frontals are markedly different  
521 from *Placosaurus* (Sullivan & Augé, 2006; see Diagnosis and descriptions here). For this  
522 reason, we proposed a new genus and species for the Cos taxon, *Sullivania gallica*.

523 *Sullivania* cannot be compared with the stratigraphically older ?*Placosaurus ragei*,  
524 from the earliest Eocene (MP 7) from Dormaal, because it is based on an isolated dentary and  
525 a parietal. For this reason, Sullivan et al. (2012) questionably assigned it to *Placosaurus*. New  
526 glyptosaurine lizard material from Dormaal, including a frontal that is different from both  
527 *Placosaurus* and *Sullivania*, is currently under study of one of us (AČ).

528 The frontals described by Rage & Augé (2003:fig. 3A) from Silveirinha (~MP 7,  
529 Portugal) as indeterminate “Glyptosaurini” (Glyptosaurinae sensu this paper) are also  
530 different from *Sullivania* in the following features: (1) the dorsal surface is covered with  
531 hexagonal osteoderms; (2) one osteoderm is located in the anterior central region, whereas  
532 posterior large ones are arranged in two rows; and (3) the frontal is robust and fused, although  
533 it is much smaller than the specimens from Cos (the minimum width of the paratypic right  
534 frontal of *Sullivania* is 5.9 mm, whereas the width of the fused paired frontals from  
535 Silveirinha is 4.5 mm).

536 **European *Sullivania* compared to North American *Gaultia***—The clade  
537 Glyptosauridae first appears in the early Eocene of Europe (Rage, 2013; Sullivan, 2019). The  
538 earliest European record of glyptosaurid lizards is from MP 7 at Silveirinha and Dormaal  
539 (Rage and Augé, 2003; Sullivan, 2019; Sullivan et al., 2012). Thus, the presence of  
540 glyptosaurids is another taxon between Europe and North America during the Eocene (e.g.,  
541 the lizard *Saniwa*: Augé et al., 2022; the questionable iguanian *Tinosaurus*: Čerňanský et al.,  
542 2023; the turtle *Axestemys*: Georgalis & Joyce, 2017; many other non-congeneric but related  
543 taxa on both continents, notably charinaine snakes; Smith & Scanferla, 2021). These imply  
544 faunal exchange between North America and Europe during the late Paleocene to early  
545 Eocene. Several episodes of faunal exchange occurred between Europe and North America  
546 before and after the Palaeocene–Eocene Thermal Maximum PETM, based on mammals  
547 (DeBast & Smith, 2017; Smith & Smith, 2013; Solé et al., 2016), but known coeval Asian

548 fossil lizard record is too poor to draw any definite conclusions regarding faunal exchanges.  
549 Interestingly, the frontal of *Sullivania gallica* from France resembles *Gaultia silvaticus* from  
550 the earliest Eocene (biozone Wa-0, Willwood Formation) of Wyoming (Smith, 2009).

551 The holotype of *Gaultia silvaticus* is an incomplete fused frontal (although no  
552 evidence of a suture is apparent on the ventral surface and most of the right half of the bone is  
553 broken away, Smith, 2009: fig. 18D, Fig. 4B) diagnosed by: (1) apically flat osteodermal  
554 shields covering the frontal and (2) different division of osteodermal cover relative to the  
555 typical hexagonal one in other glyptosaurines. However, several differences are notable,  
556 especially in the distribution of osteodermal shields and their shapes; in the anterior portion,  
557 osteodermal shields are wide in *Gaultia*, mediolaterally elongated and chevron-shaped. They  
558 form several lines, with two prominent rows of osteoderms extending along the mediolateral  
559 width of the frontal. In contrast, most frontal osteoderms in *Sullivania* are anteroposteriorly  
560 elongate rather than wide and, moreover, there is the presence of leaf-shaped first central  
561 osteoderm. However, the second lateral left osteoderm crosses over the entire mediolateral  
562 width of the frontal in *Sullivania*, having contact with the right one along the mid-line, similar  
563 to that seen in *Gaultia*. The overall shape of these lateral osteoderms is different compared to  
564 the shevron-shaped osteoderms in *Gaultia*; posteriorly, the osteodermal shields in *Gaultia* are  
565 divided into convex polygons that are smaller than the chevrons. However, there is no  
566 indication of the presence of anteroposteriorly elongated, roughly trapezoidal osteoderms in  
567 the posterior region of both paratype frontals of *Sullivania*.

568 A close relationship between *Gaultia* and *Sullivania* than to *Placosaurus* and  
569 *Glyptosaurus* cannot be ruled out. Assuming that they are closely related, *Sullivania* seems to  
570 retain some characteristics from its North American ancestor. It worth noting that half of the  
571 mammal taxa from the early Eocene of North America are closely related to the mammalian  
572 taxa known from Dormaal (Gingerich & Smith, 2006). The breakup of plate-like osteoderms

573 into smaller polygonal/hexagonal osteoderms on the skull roof is likely a derived feature  
574 among glyptosaurines, in contrast to plesiomorphic type of the large dermal plates covering  
575 the skull roof (Sullivan, 1979). The Late Cretaceous *Odaxosaurus piger* retains the plate-like  
576 osteoderm pattern seen in many anguids (Meszoely, 1970; Klembara et al., 2019) and “proto-  
577 glyptosaurines” (Sullivan, 2019). The fragmentation of cephalic osteoderms seen in the early  
578 Eocene *Sullivania* and *Gaultia* may represent an intermediate stage. *Gaultia*, like *Sullivania*,  
579 has its frontal roof armor divided into heterogenous plates as in *Arpadosaurus* (see Meszoely,  
580 1970), not into discrete subequal hexagonal osteoderms as in *Glyptosaurus*,  
581 *Paraglyptosaurus*, *Placosaurus*, and other taxa (Sullivan, 1979; Sullivan & Augé, 2006).  
582 Sullivan (2019:754) considered *Gaultia* a sister taxon to Glyptosaurinae (sensu this paper,  
583 “Glyptosaurini” sensu Sullivan, 1979). Ultimately, it is a question of how Glyptosaurinae is  
584 circumscribed. At present, no phylogenetic definition of Glyptosaurinae has been put forward.  
585 There is no apparent disagreement about the intermediate morphology of *Gaultia* and its close  
586 relationship with Glyptosaurinae as circumscribed by Sullivan (1979). Sullivan (1979:15)  
587 gave “hexagonal osteoderms that cover the entire skull” as a defining feature, and since such  
588 osteoderms are only present on the parietal, not the frontal, of *Gaultia*, it would support  
589 Sullivan’s (1979) position. However, *Gaultia* clearly does not fit the definition of  
590 “Melanosaurinae” (sensu this paper, “Melanosaurini” sensu Sullivan, 1979) either. For this  
591 reason, given the close relationship between *Gaultia* and accepted members of  
592 Glyptosaurinae, we continue to follow Smith’s 2009 assignment (“Glyptosaurini” in Smith,  
593 2009). We envision a time when a robust phylogenetic hypothesis of glyptosaurine  
594 relationships exists and clade names can be redefined on that basis.

595 Hypothetically, this might raise a question whether *Sullivania* is referable to  
596 Glyptosaurinae or is a sister taxon to this clade. Again, however, the phylogenetic topology of  
597 these taxa within Glyptosauridae can be resolved only based on phylogenetic analyses. For

598 now, we decided to tentatively assign *Sullivania* to Glyptosaurinae. The phylogenetic  
599 relationships of *Sullivania* and *Placosaurus* are unknown. Taking account that the taxonomy  
600 is based on the frontal bone, *Stenoplacosaurus* from presumably the late-middle Eocene of  
601 Mongolia is morphologically more similar to *Placosaurus* (previously, it was even placed to  
602 *Placosaurus* [Sullivan & Augé, 2006] and later placed to its own genus [Sullivan & Dong,  
603 2018]) than to *Sullivania* gen. nov. Thus, an Asian origin of *Placosaurus* cannot be excluded.  
604 Owing to an incomplete glyptosaurine fossil record between the early and late Eocene in  
605 Europe, their evolution and distribution patterns between these distant regions remain largely  
606 unresolved.

607

## 608 **Varanoidea**

609 UM-COS 1009 represents a “miniature” palaeowaranid. It differs from currently  
610 known genera by the following combination of features: (1) overall small size; the frontals of  
611 *Paranecrosaurus feisti* (Stritzke, 1983), which is known only from the early–middle Eocene  
612 of Messel in Germany, are much larger (18.2 mm in the holotype and even 30.8 in the  
613 paratype; see Smith & Habersetzer, 2021); (2) the non-paired (fused) narrow frontal, as in  
614 *Palaeovaranus* Zittel, 1887–1890 (Georgalis et al., 2021) and *Paranecrosaurus feisti*  
615 (Stritzke, 1983) (Smith & Habersetzer, 2021), unlike the paired frontals in *Eosaniwa*  
616 Haubold, 1977 (Rieppel et al., 2007); (3) the type of an ornamentation. Its ornamentation,  
617 which consists of small, densely arranged mounds, slightly resembles that of *Palaeovaranus*  
618 *lismonimenos* Georgalis, Čerňanský & Klembara, 2021 (Georgalis et al., 2021).  
619 *Palaeovaranus lismonimenos* was previously reported from the late Eocene (~ MP 17, see  
620 Georgalis et al., 2021), whereas the Cos frontal is much older. However, the detailed surface  
621 texture is different – the ornamentation of the Cos specimen is more complex, having also  
622 several spikes forming each mound (rather than possessing more-or-less simple mounds). The

623 ornamentation of UM-COS 1009 differs from the distinct sculpturing pattern observed on the  
624 frontal of the holotype of *Melanosauroides giganteus* Kuhn, 1940 from Geiseltal. The dorsal  
625 surface of the frontal of *M. giganteus* possesses broad, apically flat, rugose patches that  
626 appear to be fused broad (not distinctly keeled) osteoderms (Georgalis, 2017; Smith &  
627 Habersetzer, 2021). The dorsal surface of the frontal of *Paranecrosaurus* Smith &  
628 Habersetzer, 2021 frontal is also different (Smith & Habersetzer, 2021); and (4) the long  
629 posterolateral process relative to the the overall size of the frontal, as *Paranecrosaurus* (Smith  
630 & Habersetzer, 2021), and unlike the short process in *Palaeovaranus* (Georgalis et al., 2021)  
631 and *Eosaniwa* (Rieppel et al., 2007).

632           UM-COS 1009 represents most likely a new taxon, but the taxonomy of  
633 palaeoaranids is now mainly based on the parietal morphology (Georgalis et al., 2021). For  
634 this reason, we identified this frontal only as Palaeoaranidae indet.

635           It is unclear whether the maxilla (UM-COS 1010) and the frontal (UM-COS 1009)  
636 represent a single taxon, although they are comparable in size and come from the same  
637 locality. The overall morphology and plicidentine support allocation of the maxilla to a  
638 varanoid (Kearney and Rieppel, 2006; Georgalis & Scheyer, 2019). It cannot be referred to  
639 Shinisauridae, a group of anguimorph presence that is well-documented from the Eocene of  
640 Europe (Smith, 2017; Smith et al., 2018). The maxilla has several teeth posterior to the last  
641 labial foramen where at least four tooth positions are preserved. This condition resembles  
642 *Saniwa orsmaelensis* Dollo, 1923, which is known from Dormaal (Augé et al., 2022). Indeed,  
643 the teeth and the concave lateral surface (the posterior portion of the maxilla is slightly bent  
644 laterally) of the Cos specimen resemble the condition in this taxon (Augé et al., 2022: fig. 2).  
645 The geological age of the maxilla would also be consistent with the presence of *Saniwa* in  
646 Cos. However, several tooth positions posterior to the last labial foramen are also present in  
647 *Paranecrosaurus feisti* (Smith & Habersetzer, 2021). The diagnostic parts of palaeoaranid

648 maxillae, however, are mainly found in medial view. The presence of a distinctly developed  
649 nasal crest on the dorsomedial surface of the nasal process is a distinguishing feature of  
650 *Palaeovaranus* (Georgalis et al., 2021) and *Paranecrosaurus* (nasolacrimal ridge sensu Smith  
651 & Habersetzer, 2021). Unfortunately, this portion in the Cos maxilla is heavily damaged and  
652 there is no indication of its presence. The teeth and the overall shape of the Cos specimen are  
653 also similar to *Melanosauroides* Kuhn, 1940 (see Georgalis, 2017: fig. 4B). For all these  
654 reasons, caution is needed and we decided to identify this maxilla only as Varanoidea indet.  
655 (although we cannot be sure if palaeovaranids are indeed varanoids). More complete material  
656 from Cos will shed light on the diversity of the varanoids here.

657

658

#### ACKNOWLEDGMENTS

659 For access to this fossil material and help, we thank Mehdi Mouana (Institut des  
660 Sciences de l'Evolution de Montpellier, France). For English correction and helpful advice,  
661 we are indebted to Robert M. Sullivan (New Mexico Museum of Natural History and Science,  
662 USA) and Hans-Dieter Sues (Editor). For advice, we thank Georgios Georgalis (Polish  
663 Academy of Sciences), Krister Smith (Senckenberg Research Institute, Frankfurt am Main),  
664 Thierry Smith and Annelise Folie (both Royal Belgian Institute of Natural Sciences,  
665 Brussels). We thank Nour-Eddine Jalile (MNHN) for permissions and sending us additional  
666 photographs of specimens under their care. The photographs were taken by Philippe Loubry.  
667 For critically reading the manuscript, we thank Hans-Dieter Sues (Editor), Georgios Georgalis  
668 (Polish Academy of Sciences, Poland) and one anonymous reviewer. This work was  
669 supported by the Scientific Grant Agency of the Ministry of Education of Slovak Republic  
670 and Slovak Academy of Sciences, Grant Nr. 1/0191/21 (to A. Č).

671

672 AVAILABILITY OF MATERIALS AND DATA

673 All specimens are catalogued and accessible in the fossil reptile collection of the University of  
674 Montpellier in France. Digital surface models of the figured fossil specimens are available on

990

991 FIGURE 1. Location of the Cos locality in France. [planned for 2/3 of full-page width]

992

993 FIGURE 2. *Sullivania gallica* gen. et sp. nov. from the early Eocene Cos locality of France.

994 UM-COS-1001 (holotype) anterior portion of fused frontals: in **A**, dorsal; **B**, outline drawing

995 showing the armour division pattern; **C**, ventral; and **D**, lateral views (all micro-CT

996 visualizations). **E**, axial section at the mid-level of the dorsoventral thickness; and **F**, coronal

997 section at the level of the frontal cranial crests. [planned for page width]

998

999 FIGURE 3. *Sullivania gallica* gen. et sp. nov. from the early Eocene Cos locality of France.

1000 UM-COS-1000 (paratype), nearly complete right frontal: in **A**, dorsal; **B**, photograph with

1001 line drawing indicating the interpretation of osteoderm distribution; **C**, ventral; and **D**, lateral

1002 views (micro-CT visualizations). **E**, Axial section at the mid-level of the dorsoventral

1003 thickness; and **F**, coronal section at the level of the frontal cranial crests. UM-COS-1003

1004 (paratype), posterior portion of right frontal: in **G**, dorsal; and **H**, ventral views (all micro-CT

1005 visualizations). [planned for page width]

1006

1007 FIGURE 4. The reconstruction of complete frontal of *Sullivania gallica* gen. et sp. nov.

1008 comparing it to frontals of *Gaultia silvaticus*, from the earliest Eocene of Wyoming, USA;

1009 *Placosaurus estesi* and *P. rugosus*, from the middle and late Eocene of France; and

1010 *Stenoplacosaurus mongoliensis* from the late-middle Eocene of Mongolia (all are dorsal

1011 views, except G, which is left lateral view). **A**, *Sullivania gallica*, reconstruction based on

1012 UM-COS-1000 and 01; **B**, *Gaultia silvaticus* UCMP 216000, (holotype) middle portion of  
1013 frontal and **C**, UCMP 150966 (paratype) partial left frontal (modified from Smith, 2009); **D**,  
1014 *Placosaurus estesi* (MNHN QU-17735, holotype) nearly complete frontal; **E**, *P. rugosus*  
1015 (MNHN 1906-25, holotype) nearly complete frontal and left prefrontal; and **F**, **G**,  
1016 *Stenoplacosaurus mongoliensis* (AMNH 6669, holotype), left frontal (modified from Sullivan  
1017 & Dong, 2018). The arrow in *Gaultia* (**B**) indicates the position of the mid-line between the  
1018 left and right frontals (see Smith, 2009). The dotted line in *P. rugosus* (**E**) indicates the frontal  
1019 – prefrontal contact. [planned for page width]

1020

1021 FIGURE 5. Glyptosauridae indeterminate from the early Eocene Cos locality of France. UM-  
1022 COS-1002 left maxilla. **A**, left lateral view; **B**, medial (lingual) view; **C**, occlusal (ventral)  
1023 view; and **D**, dorsal view. **A-D** are micro-CT visualizations; UM-COS-1011, right maxilla. **E**,  
1024 right lateral view, **F**, medial (lingual) view, **G**, occlusal (ventral) view (with close-up of teeth  
1025 in ventromedial view); and **H**, dorsal view. [planned for page width]

1026

1027 FIGURE 6. Glyptosauridae indeterminate (**A-J**) and Anguioidea indet. (**K-M**) from the early  
1028 Eocene Cos locality of France. Isolated cephalic osteoderms. UM-COS-1004, hexagonal  
1029 osteoderm: **A**, dorsal; **B**, ventral; and **C**, lateral views. UM-COS-1005, polygonal osteoderm:  
1030 **D**, external and **E**, internal views. Isolated body osteoderms. UM-COS-1006: **F**, external; **G**,  
1031 internal and **H**, lateral views. UM-COS-1007: **I**, external; and **J**, internal views. UM-COS-  
1032 1008; **K**, external; **L**, internal; and **M**, oblique lateral views. All images are micro-CT  
1033 visualizations. [planned for page width]

1034

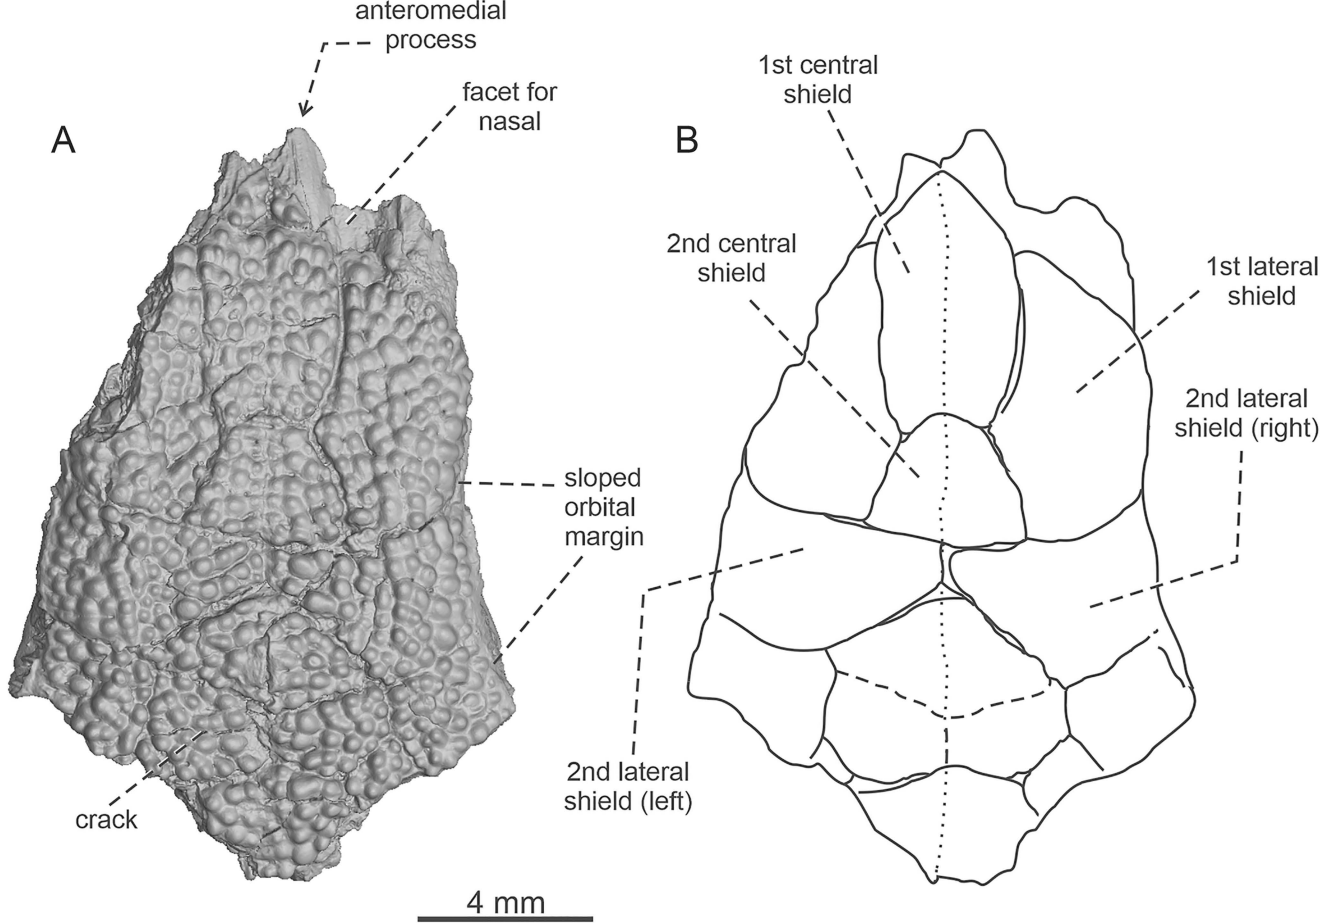

1035 FIGURE 7. Palaeovaranidae indeterminate from the early Eocene Cos locality of France.  
1036 UM-COS- 1009, nearly complete frontal. **A**, dorsal; **B**, ventral; **C**, left lateral; **D**, right lateral;  
1037 and **E**, anterodorsal views. All images are micro-CT visualizations. [planned for page width]

1038

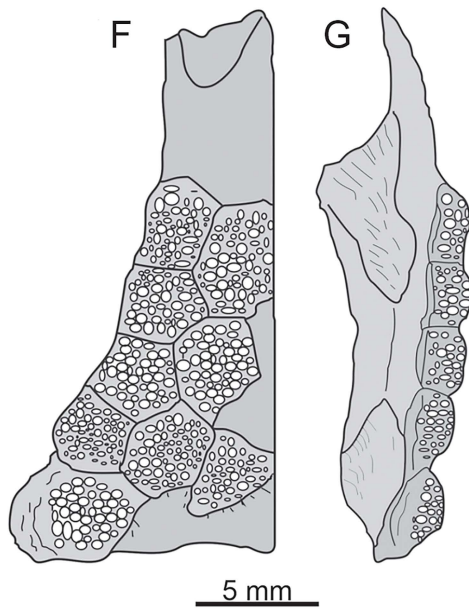

1039 FIGURE 8. Varanoidea indeterminate from the early Eocene Cos locality of France. UM-  
1040 COS-1010, left maxilla. **A**, lateral; **B**, medial; **C**, dorsomedial; **D**, dorsal; and **E**, ventral views  
1041 (**A-E** are micro-CT visualizations); and **F**,  $\mu$ CT slice of tooth bases showing the presence of  
1042 plicidentine. [planned for page width]
